*"To the solid ground
Of Nature trusts the mind which builds for aye."*—WORDSWORTH

THURSDAY, MAY 3, 1883

LIFE OF SIR WILLIAM ROWAN HAMILTON

Life of Sir William Rowan Hamilton, Andrews Professor of Astronomy in the University of Dublin, and Royal Astronomer of Ireland; including Selections from his Poems, Correspondence, and Miscellaneous Writings. By Robert Perceval Graves, M.A., Sub-Dean of the Chapel Royal, Dublin. Vol. I. pp. 692. (Dublin University Press Series, 1882.)

WE are glad to welcome the appearance of the first volume of this work, which has long been eagerly watched for by those interested in the career of the wonderful genius whose life is here narrated. To many readers this volume will afford material for no little surprise. Sir William Rowan Hamilton is known to fame as a mathematician. He is known by his memoirs on systems of rays; by his discovery of the great dynamical generalisation which is implied in his theory of the characteristic function; by his exquisitely beautiful prediction of the phenomena of conical refraction; and above all by his theory of quaternions—an imposing mass of profound thought which must be ranked with the very greatest mathematical achievements of any age or nation. Yet here we have a very portly volume of almost seven hundred pages, of which only an extremely small fraction is devoted to Hamilton's mathematical work. The progress of his papers on rays is here and there referred to, and there is an interesting historical chapter on conical refraction, but we may turn in vain to the index for a reference to quaternions, and we have only noticed the word occurring once or twice in the entire volume. But the surprise will disappear when the reader begins to make acquaintance with the volume. He will then see that Hamilton's mathematical labours were only one of the forms in which his most extraordinary genius was manifested. He will see that the early years of Hamilton's life afforded such copious materials to a biographer that the present volume only extends to the time when Hamilton had attained the age of twenty-seven, and that the crowning achievement of quaternions by which Hamilton is best known was the fruit of his riper years, and belongs to his subsequent career.

At the Cambridge meeting of the British Association in 1833, Prof. Sedgwick spoke of Hamilton—then twenty-eight years old—as "a man who possessed within himself powers and talents perhaps never before combined within one philosophical character." The volume before us bears testimony which would go a long way towards justifying this eulogium. We think that Sir W. Hamilton has been fortunate in having a biographer so careful in his facts and so skilful in the manipulation of his copious materials as Mr. Graves has proved himself to be. Hamilton had the habit of putting on record very minute circumstances. He preserved copies of a large proportion of the letters and notes written by him, whether important or not; he often recorded the hour at which they were despatched, and the person to whom they were intrusted for the post. The enormous mass thus accumulated during a long and very studious life were left at Hamilton's death in a state of utter confusion, and it has been the laborious duty of his biographer to extract from the mass those materials which were suitable for his purpose. The very extensive correspondence of Hamilton is also a source from which his biographer has obtained much aid. Of his own qualifications for the task the biographer thus modestly expresses himself in the preface:—

"The public has some right to inquire why one who has to confess himself to be no mathematician should have undertaken the present work. To such an inquiry I may reply as follows: that although unconnected with Sir W. R. Hamilton by any tie of kindred, I became his friend in the youth of both of us, and that our friendship continued unbroken till the day of his death; that when he was applied to by the Editor of the *Dublin University Magazine* in 1841 to name a friend who should be requested to supply to that magazine a biographical sketch for insertion in its portrait gallery of distinguished Irishmen, he did me the honour of designating me, and furnished me with the necessary facts; that he afterwards sought my consent to his nomination of me as his literary executor,—a nomination however which, he told me afterwards, he thought right to withhold when he found that the remainder of my life would probably be spent in England, and that I should therefore be unable to fulfil

the duties of the trust without undue inconvenience. Lastly, that after his death I was asked by his sons to undertake the task, and was at the same time informed by several of the most influential of his friends that this selection met their approval, and that they were willing to trust to my judgment the correspondence over which they had control."

William Rowan Hamilton was born in Dominick Street, Dublin, on August 3-4, 1805. His father, Archibald Hamilton, was a solicitor. When the boy was little more than a year old, it would seem that he gave such indications of unusual talent that his parents decided to commit the education of the child to his uncle, the Rev. James Hamilton of Trim, a man of very remarkable talents, who, with his sister, Jane Sydney Hamilton, reared and educated the child. What that childhood was can be best described in the words of the biographer, who says, on pp. 46-47:—

"It will then be noted that, continuing a vigorous child in spirits and playfulness, he was at three years of age a superior reader of English and considerably advanced in arithmetic; at four a good geographer; at five able to read and translate Latin, Greek, and Hebrew, and loving to recite Dryden, Collins, Milton, and Homer; at eight he has added Italian and French, and gives vent to his feelings in extemporised Latin; and before he is ten he is a student of Arabic and Sanscrit. And all this knowledge seems to have been acquired not indeed without diligence, but with perfect ease, and applied, as occasion arose, with practical judgment and tact; and we catch sight of him when only nine swimming with his uncle in the waters of the Boyne. In this accomplishment he afterwards became a proficient."

Again, on p. 51 we have a description of a little manuscript book of 30 pages thus entitled "A Syriac Grammar. In Syriac Letters and Characters; Compiled from that of Buxtorf; Translated into the English Language and Syriac Characters by William Hamilton, Esq., of Dublin and Trim. Begun July 4th, 1817; Finished July 11th, 1817." The conclusion of the book is as follows:—"Thus have I gone through what is necessary to be known for reading and writing Syriac. . . . Soon may be expected an account of their irregular and indeclinable words, &c., with a syntax." The author of this production was still under twelve years old.

A couple of years later (November, 1819) we find Hamilton inditing a letter in Persian to the Persian ambassador, Mirza Abul Hassan Khan, then on a visit in Dublin. Hamilton has left a translation of this production, the following extract from which evinces the Oriental aroma which pervades the whole:—

"As the heart of the worshipper is turned towards the altar of his sacred vision, and as the sunflower to the rays of the sun, so to thy polished radiance turns expanding itself the yet unblossomed rosebud of my mind, desiring warmer climates whose fragrancy and glorious splendour appear to warm and embalm the orbit about thee, the Star of the State, of brilliant lustre."

Hamilton's letter met with a very favourable reception; the secretary had observed no mistakes, and inquired whether he had not copied it from something, and the compliments bestowed on the author were all the more pointed, because "Captain Kian," who had also attempted to write a letter in Persian, was informed that his presence would be dispensed with, as *his* letter was totally unintelligible.

A large fraction of the present volume is filled with the poetical effusions, in which on all occasions Hamilton was prone to indulge. The first traces of these "showers of verse," as Wordsworth afterwards playfully called them, is found in Hamilton's letters to his sisters. The biographer has not, however, deemed it desirable to record any poetical effort prior to his sixteenth year, and the first piece we find is (p. 95) "To the Evening Star," of which the first stanza is—

"How fondly do I hail thee, Star of Eve,
In all thy beauty sinking to the west,
And as if loth our firmament to leave
Slow and majestic sinking to thy rest."

Hamilton lived and thought in an atmosphere of poetry; he wrote poems on all occasions and all sorts of subjects. It was perhaps not unnatural that as a disappointed lover he should bewail his sorrows in verse, that he should write birthday addresses to his sisters, and sonnets on the Beauty of the Dargle, but we also find him addressing an "Ode to the Moon under Total Eclipse," and to use his own words in writing to Wordsworth, "I have always aimed to infuse into my scientific progress something of the spirit of poetry, and felt that such infusion is essential to intellectual perfection." He has, however, indicated very clearly where his real ambition lay, for at the age of twenty, writing to his friend, Miss Lawrence, he says:—

"But while you concur with my own sober judgment in refusing to award me the crown of poetic power you would not I am sure desire to extinguish in me that love of 'sacred song' to which I can with truth lay claim. There is little danger of its ever usurping an undue influence over a mind that has once felt the fascination of science. The pleasure of intense thought is so great, the exercise of mind afforded by mathematical research so delightful, that having once fully known it, it is scarce possible ever to resign it. But it is the very passionateness of my love for science which makes me fear its unlimited indulgence. I would preserve some other taste, some rival principle; I would cherish the fondness for classical and for elegant literature which was early infused into me by the uncle to whom I owe my education, not in the vain hope of eminence, not in the idle affectation of universal genius, but to expand and liberalise my mind, to multiply and vary its resources, to guard not against the name but against the reality of being a mere mathematician."

A year later (1822) we find Hamilton entering upon the path of original mathematical discovery. The title of one of the first of these early papers is "Examples of an Osculating Circle determined without any Consideration repugnant to the utmost rigour of Analysis." With two others, one on "The Osculating Parabola to Curves of Double Curvature," and the other on "The Contacts between Algebraic Curves and Surfaces," Hamilton paid his first visit to Dr. Brinkley, then the Astronomer Royal of Ireland. Dr. Brinkley was impressed by their value and by the genius which at the age of seventeen had produced work of so much originality.

The first year of Hamilton's career in Trinity College, Dublin (1824), justified all the expectations entertained by his friends. In his Freshman year he distanced all his competitors alike in classics and in mathematics, while he was also awarded a Chancellor's prize for his poem on the subject of the Ionian Islands. In the same year we read that he commenced another friendship, which remained unbroken to the end of the long life of the brilliantly gifted Maria Edgeworth, and which brought to Hamilton

many of her delightful notes and letters, and in them cordial sympathy and wise counsel. Of Hamilton Maria Edgeworth writes: "Mr. Butler came with young Mr. Hamilton, an 'admirable Crichton' of eighteen, a real prodigy of talents, who, *Dr. Brinkley says, may be a second Newton.*"

At the age of twenty-one came the turning-point in Hamilton's career—his appointment to be Andrews Professor of Astronomy in the University of Dublin, and Royal Astronomer of Ireland. The vacancy arose from the promotion of Brinkley in 1826 to be the Bishop of Cloyne. The following incident of the occasion is given by his biographer:—

"Candidates for the post came over from England, among them Mr. Airy of Cambridge (already distinguished by his Senior Wranglership and by optical researches), and some who had already gained the rank of Fellow in Hamilton's own college were competitors. It appears that before the end of April he met Airy and other eminent men at the table of Dr. Lloyd, and we remember hearing that, in the scientific discussion to which the meeting gave occasion, he took his part with striking ability, modesty, and firmness, when it became necessary to defend some of his optical results against the objections of Mr. Airy."

Hamilton seems to have felt that it would be presumptuous for an inexperienced undergraduate to put himself forward as a candidate; he therefore retired to the country to carry on quietly his work for the classical medal. It was only a week before the appointment had to be made that he received at Trim, from his tutor, Mr. Boyton, an intimation that the Board were favourably disposed towards him, and urging him to come up at once to take the advice of his friends. That advice concurring with the strong opinion of his zealous friend and tutor, he was unanimously appointed on June 16, 1827.

A few months later Hamilton paid a visit to Keswick, and commenced his memorable friendship with Wordsworth. That the philosopher and the poet were mutually interested is manifest from Hamilton's account written in a letter to his sister Eliza:—

"He (Wordsworth) walked back with our party as far as their lodge, and then, on our bidding Mrs. Harrison good night, I offered to walk back with him while my party proceeded to the hotel. This offer he accepted, and our conversation had become so interesting that when we arrived at his home, a distance of about a mile, he proposed to walk back with me on my way to Ambleside, a proposal which you may be sure I did not reject, so far from it that when he came to turn once more towards his home I also turned once more along with him. It was very late when I reached the hotel after all this walking."

Hamilton quickly followed up his introduction to Wordsworth by sending him an original poem entitled "It haunts me yet." Wordsworth replies:—

"With a safe conscience I can assure you that in my judgment your verses are animated with the poetic spirit, as they are evidently the product of strong feeling. The sixth and seventh stanzas affected me much, even to the dimming of my eyes and faltering of my voice while I was reading them aloud. Having said this I have said enough. Now for the *per contra.* You will not, I am sure, be hurt when I tell you that the workmanship (what else could be expected from so young a writer?) is not what it ought to be. . . ."

"My household desire to be remembered to you in no formal way. Seldom have I parted—never, I was going to say—with one whom after so short an acquaintance I lost sight of with more regret. I trust we shall meet again."

The biographer adds that Wordsworth has said in his hearing that Coleridge and Hamilton were the two most wonderful men, taking all their endowments together, that he had ever met.

At the commencement of his career at the Observatory Hamilton entered with diligence into the practical work of observing, but it would seem that the necessary exposure told injuriously on his health. It does not appear that he made any observations of importance. His tastes pointed strongly in the direction of mathematical research, and the development of his discoveries occupied more and more of his time, until at length, with the full consent of the authorities of the University, Hamilton practically relinquished all observatory work and gave his splendid mathematical genius full scope. Unquestionably this was the best course for the credit of Hamilton himself, best for the credit of his University, and best for the interests of science. Hamilton could never have made even a moderately successful practical astronomer. He tells Dr. Robinson that he disliked observing; he was essentially a man of speculation rather than of action. Like his friend De Morgan, Hamilton was not "a man of brass, a micrometer-monger, a telescope-twiddler, a star-stringer, a planet-poker, or a nebula-nabber"—he had none of the qualifications necessary for a routine of observatory work. His workshop was his study, where he sat immersed in what he calls his "mathematical trances" and elaborated his great discoveries.

The latter half of the volume describes his early life at the Observatory. He was fortunate in obtaining as a pupil Lord Adare, afterwards Earl of Dunraven, between whom and Hamilton a lifelong friendship of the tenderest character arose. Many other friendships are here copiously illustrated by the letters which have been preserved. The letters to and from Sir J. W. Herschel and Sir G. B. Airy relate chiefly to the discussion of Hamilton's labours on the systems of rays and other matters of purely scientific interest; but there are stores of other letters. The voluminous correspondence between Hamilton and Wordsworth will itself possess a wide interest even in circles where Hamilton's more serious labours are unknown. There are letters to and from Coleridge, as well as many others relating to purely literary matters. There is an extensive correspondence with Dr. Robinson, in which the Armagh astronomer gives kindly counsel to his younger brother at Dunsink. There is the correspondence with his friend, Aubrey de Vere. There are the numerous letters to his lady correspondents, to his sisters, to Maria Edgeworth, to Lady Dunraven, to Lady Campbell, and to Miss Lawrence. Then there is the visit of Hamilton to London, chiefly for the purpose of visiting S. T. Coleridge, to whom he had an introduction from Wordsworth; and there are interesting accounts of the visits of Wordsworth to the Observatory at Dunsink, where a shady walk in the garden still bears the poet's name.

A chapter towards the close (p. 623) gives a sketch of the discovery of conical refraction made in the year 1832, while the author was still only twenty-seven. The importance of this discovery was speedily recognised, and the biographer writes: "At the Cambridge meeting of the

British Association, 1833, the attention of the mathematical and physical section was largely given to the subject, and Herschel, Airy, and others spoke warmly in praise of the discovery. In the introductory discourse with which the proceedings of that meeting was opened, Prof. Whewell made it a topic, and expressed himself in the following words: 'In the way of such prophecies few things have been more remarkable than the prediction that under particular circumstances a ray of light must be refracted into a conical pencil, deduced from the theory by Prof. Hamilton and afterwards verified experimentally by Prof. Lloyd.' Previously, in the same year, Prof. Airy had publicly recorded his impression upon the subject as follows: 'Perhaps the most remarkable prediction that has ever been made is that lately made by Prof. Hamilton.'"

The view Hamilton himself took of the discovery of conical refraction was characteristic. "It was," he writes to Coleridge on February 3, 1833, "a subordinate and secondary result when compared with the object I had in view to introduce harmony and unity into the contemplations and reasonings of optics regarded as a branch of pure science."

At the close of this volume we still leave Hamilton quite a young man. The great labour of his life has not yet commenced; its nature has not indeed even dawned upon him. We shall therefore look forward with pleasure to the continuation of the present most interesting work. The development of Hamilton's more mature genius, his correspondence with De Morgan, in itself no inconsiderable mass, and above all the gradual evolution of quaternions, will form most attractive materials for his biographer.

It is by the liberality of the Board of Trinity College, Dublin, that the present instalment of the work has been brought out, and we sincerely trust that the same liberality will be extended to enable the biographer to continue to do real justice to his subject. But besides the present work another debt is due to his memory. Hamilton's earlier papers are very inaccessible: many of them are scattered about in various periodicals, and his two noble treatises on quaternions are out of print. A complete edition of Hamilton's works would be an appropriate sequel to this biography, and they would be not unfitting companions for the works of Lagrange and of Gauss. It is not often that a University has so gifted a son as Hamilton. Let us hope that the University which is proud to claim him will see fit to raise this further monument to his genius.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*

[*The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to insure the appearance even of communications containing interesting and novel facts.*]

Sheet-Lightning

In Nature, vol. xxvii. p. 576, a statement is made that the "opinion so long and generally entertained" that "sheet-lightning and the so-called summer or heat-lightning are nothing else than the reflection of, or the illumination produced by distant electrical discharges, is not supported by observation." This statement surprises me, for I should have said that the opinion once commonly entertained that sheet-lightning is a distinct form of lightning unaccompanied by sound, is now for the most part rejected, the results of observation being distinctly against it. The question is an old one; but as the writer of the above statement only refers to the observations made at Oxford during the twenty-four years ending 1876, I will confine myself in the main to an examination of these. I must premise that I do not assert that lightning never occurs at such an altitude that the thunder accompanying it is not audible. In rare instances in Europe lightning is observed in the zenith, followed after an interval of twenty seconds or more by faint rolling thunder immediately overhead. It is therefore antecedently probable that lightning may occur at too great an elevation for the thunder to be heard at the earth's surface at all; and this is especially likely to happen in some of those thunderstorms within the tropics, the altitude of which is extremely great.

The distance at which the illumination produced by lightning in a dark night can be observed depends upon the altitude and the intensity of the discharge, and further upon the altitude, character, and amount of the clouds. It is possible that the diffused particles of ice (at a much greater altitude than the cirri), which produce the phenomenon called "rayons du crépuscule," are capable in some cases of reflecting the illumination. However this may be, it is certain that the illuminations of an ordinary thunderstorm at midnight, when there is no moonlight, have an average radius of more than forty miles. The distance at which thunder is heard depends on a variety of conditions; but we may safely state that in the open country in calm weather at midnight the sound is rarely heard at a greater radius than fifteen miles. At the Radcliffe Observatory, which is scarcely out of the reach of rumbling sounds produced by the traffic of a town, the average distance at which thunder is distinguished may probably be safely reduced to seven miles. Assuming then that at Oxford the area of illumination has a radius of forty-two miles, and that of thunder one of seven miles (and in this assumption we are probably not very far from the truth), we conclude that in the darkest hours "lightning without thunder" should occur at Oxford with a frequency which is expressed by the figures 35 : 1 as compared with "thunder with or without lightning." A deduction ought, of course, to be made for the effects of moonlight. But when this has been made, the figures quoted by your reviewer are not only satisfied by the hypothesis for the refutation of which he employs them, but further, if his mode of reasoning were legitimate, they would lead us to the conclusion that in nearly seven cases out of eight the thunder heard at Oxford is not the result of electrical discharge at all! Such thunder does not occur elsewhere, and was not in vogue at Oxford "in my time."

Practically, however, two considerations must not be omitted: (1) some localities enjoy a special immunity from thunderstorms, while others are responsible for the production of an exceptionally large number; in the former the frequency of illumination will be greater in comparison with the frequency of thunder, in the latter it will be less: (2) (and this is a consideration of much more importance, though frequently neglected when a conclusion is deduced from records of phenomena) the relative frequency of two sets of *occurrences* often differs widely from the relative frequency of the *records* of the occurrences. The relative frequency of records of thunder and of lightning is to a large extent dependent on the position of the observer's residence, his habits, the keenness of his eyes and ears respectively, and his attentiveness to the impressions which those organs respectively experience.

No one who has on a summer night carefully watched the gradual approach of a great thunderstorm, counting the flashes, and registering the time-interval and number of claps from the minute when the first flickers begin above the southern horizon to that at which the storm is in its full roar and rattle overhead; no one who in a long night journey by train has run into a thunderstorm whose distant coruscations he has noticed two or three hours beforehand; no one, at least, who after watching sheet-lightning in one particular direction has made careful inquiries as to the occurrence or otherwise of thunder over the district from which the light proceeded, will hesitate in pronouncing the verdict that ordinary sheet or summer lightning is simply the illumination produced by a distant thunderstorm.

W. Clement Ley

St. Andrews

ST. ANDREWS is the one rural university in Scotland. Its small constituency is of a somewhat peculiar kind, drawn from many sources, not by mere "gravitation," but by natural choice, and probably would not follow it if removed to a town. When the Tay Bridge has been set up again, St. Andrews will be within thirty-five minutes of Dundee. The changes which may result from this are difficult to forecast. Meanwhile the University is doing, although a limited, yet a good and useful work, and is blessed with many distinguished sons. If the career of each of these men could be traced from the Peebleshire U.P. manse, or the Forfarshire village schoolhouse, or the Cupar building-yard, to the place in life which they now fill and adorn, the history would be in many ways instructive, and it would be seen that the ideal of a "ladder" of merit (for lads of merit) is to some extent realised north of the Tweed.

The English universities, with all their wealth and all their noble endeavours, have never yet, like those in Scotland, had "their root spread out by the waters" of the life of the people. The Scottish universities fulfil the Christian precept of asking the poor to their feast. But as a consequence of this they have few rich friends, and have the more need of being visited with "the dew of heaven from above."

St. Andrews, however, has been unfairly dealt with in a special way, and it is an unfairness which can be remedied under the present Bill without making any demand upon the public funds. Three of her Chairs and more than half of her bursaries were left by the Commissioners of 1858 under the care of private patronage. The removal of this blot would inevitably be followed by an accession of healthy life. And the place is already by no means deficient in corporate vitality. Its undergraduates, numbering a few more than those at Exeter College, Oxford, and a few less than those at Balliol or Christ Church, have their football club, golf club, gymnastic club, two debating societies, musical association, domestic and Shakespearian association, and others, to which has recently been added a volunteer artillery corps. At football they have somehow managed to hold their own against the larger universities. Suppose that by the efforts of the new Commission some *Concordat* were arranged between this old yet vigorous life and the Herculean infant across the Tay, that by this means a complete Science Faculty could be established in this part of Scotland, and a new development given to the already existing St. Andrews Science Degree, would there not be then a promise for the future?

In spite of rail and telegraph, the feline attachment to places is still shared by man. To deracinate is easier than to plant, easier to plant than to make what is planted grow. Wise statesmanship will follow nature, and avail itself of elements which exist, if only life is found in them.

To return to the more general aspect of the question: the Scottish Universities have a claim to State recognition which has hardly been sufficiently considered. They are the spiritual progenitors (" though honest, yet poor," like Launcelot Gobbo's father) of all University life in Great Britain that does not directly flow from Oxford and Cambridge (see the *New Monthly Magazine* for the year 1825), and for much of this too. Prof. Stuart of Cambridge is a St. Andrews man. Had he been an Etonian or Harrovian it is not too much to say that the higher education in many English towns would be in a different position from that on which they congratulate themselves to-day. X.

Cape Bees and "Animal Intelligence"

I KEEP a large number of hives, chiefly of Cape bees, and find that their habits closely resemble those of European honey-bees; but in the course of my observations I have met with an instance of sagacity on the part of Cape bees, which, although it may also have been observed with regard to European or American bees, has not, so far as I am aware, been recorded in any treatise upon the subject. Last year my gardener hived a swarm of bees, which were not however satisfied with their new hive, their scouts having probably already selected some hollow tree for their future habitation. They accordingly left, but were soon again secured. In order, if possible, to prevent their deserting the new hive, I placed the queen in a queen-cage (a small perforated metal box with circular holes of the diameter of an ordinary pin's head), which I fixed to the roof inside the hive. A few days afterwards there were several honeycombs in the hive, and in most of the cells eggs had been deposited. Now there could be only three ways of accounting for these eggs in the cells: there might have been more than one queen in the swarm, or there might have been an egg-laying neuter among them, or else the eggs must have been those of the imprisoned queen. Accordingly I several times examined the swarm and the honeycombs (the hive being a frame hive), and satisfied myself that there was no other queen in the swarm. The queen was kept in the cage until some of the larvæ had come to maturity, the bees of course feeding her through the holes of the cage, and I found that the young bees were neuters, and not drones as they would have been if the eggs had been laid by a neuter. The only explanation, therefore, of the presence of the eggs in the cells was that they had been laid or passed by the queen through the holes of the cage, and taken up and deposited in the cells of some of the workers. This performance showed so much sagacity on the part of the bees, especially the mother bee, that I subsequently repeated the experiment with eight other swarms, and in two instances there was an exactly similar result. Two of the six remaining swarms were so dissatisfied with the new hives offered to them that they refused to build any comb, and ultimately deserted the hive, leaving the caged queen behind, although I was quite satisfied that neither swarm had a second queen among their number. I may here remark that it is much more difficult to retain a swarm of Cape bees in an artificial hive selected for them than appears to be the case in Europe or America, the explanation perhaps being that they are not sufficiently domesticated, and prefer being queenless in a natural hive selected by themselves to remaining with their imprisoned queen in a hive they do not approve of. It is possible of course that the two swarms which left their queen behind may have joined some other occupied hives or may have returned to their own former hive; but I may state that on each occasion I had removed the hives from which the swarms had issued to a considerable distance from their former position. The four remaining swarms upon which I experimented were satisfied with their new hives and built combs, but no eggs were found deposited in the cells. One of these swarms had an imported fertile Italian queen; the second and third had Cape queens, and the fourth had an Italian queen, the progeny of the imported one; the three first began laying in the cells soon after being released, but the fourth never laid eggs at all. As to the last of these queens, I fear she was rather roughly handled when caught, and that this may explain her not laying at all; but I may add that I have not yet succeeded in obtaining queens proved to be fertile from among the progeny of imported Italian queens. There are very few Italian drones in the colony, or at all events in the neighbourhood of Cape Town, and if the Cape drone does not cross with the Italian queen this would be a sufficient explanation of my failure. While upon this subject I may state that we have a yellow bee in South Africa somewhat resembling the Italian, but the neuters are a little smaller. They more closely resemble the Egyptian bees, judging by the descriptions I have read of the latter; but some of their habits are different, for they have only one queen in a hive, and they gather and use propolis, which the Egyptians are said not to do. But most of our Cape bees rather resemble the English bee, although considerably smaller, and the rings of their abdomen are of a lighter brown colour, and I confess till a few years ago I was not aware that we had any other variety. To my surprise, however, about three years ago a swarm of the yellow-winged bees arrived at my place. At first I took them to be Italians, but I had not yet then imported any myself, nor have I since been able to discover that any one else had done so. The queen and drones were exactly like the Italian queen and drones, but the neuters were a little shorter and more slender. I have unfortunately not secured any fresh swarms from the one which I hived, but the neuters that are now in the hive cannot be distinguished from the ordinary Cape worker. There are not at present any drones in the hive, and, as the hive has no frames, it is difficult (without first driving the swarm) to discover whether the queen, now in the hive, has the same appearance as the one which originally arrived. Strangely enough I continually find drones of the yellow variety in hives of the ordinary Cape brown bee. I sometimes, but rarely, see yellow workers visiting my flowers and fruit, and on a recent visit to Natal I saw numbers of bees visiting a sugar store in Durban, all of which were of the yellow variety. I was not sufficiently long in Natal to be able to say whether there are any of the ordinary Cape bees in that colony, but in the Transvaal I have seen both varieties in the fields.

Before concluding I wish, with your permission, to make a

few remarks upon a passage in Mr. Romanes' very interesting book on "Animal Intelligence." At p. 188 he says: "Bee-masters who attend much to their bees, so as to give the insects a good chance of knowing them, are generally of the opinion that the insects do know them, as shown by the comparatively sparing use of their stings." If by this he means that the bees recognise and become accustomed to the scent of persons who attend much to them, I quite agree with him, but I do not believe that their recognition goes any further. I keep two apiaries at a considerable distance from each other, to one of which my gardener, a coloured Malay, attends, and to the other a Kafir labourer. At first they were generally stung when passing too near the entrance of a hive, but now they pass and repass with impunity. They work with the bees more frequently than I do, and yet when either of them assists me in his own apiary, he receives more stings than I do. This I ascribe to the gardener's using snuff in his mouth very freely, and to the Kafir's very pronounced odour. To test the recognition of the bees I once requested the Malay and the Kafir to change clothes with each other, and wear thick veils over their heads and faces. They did so, and assisted me first in the apiaries to which they were respectively in the habit of attending, with the result that they received no stings, but when either began to work with the bees in the apiary he usually did not attend to, he was so stung about the hands that he had to beat a hasty retreat, whilst I remained uninjured, although not veiled. The two men are almost of the same size and build, so that if the bees had any power of general recognition they would probably (as some of the other servants did) have mistaken the one for the other. I can, therefore, only account for the conduct of the bees by the unpleasant, and to them strange, odour. At my request the gardener discontinued the use of snuff in his mouth for some time, and during that time he was not stung more than I was while working with bees, but if the Kafir stands before the entrance of an unaccustomed hive he is remorselessly stung. I may add that Cape bees are very much more vicious than European ones seem to be, and that, if not skilfully handled, they will unmercifully sting their most familiar friends. On one occasion a bunch of carrots was left near the gardener's apiary, which so enraged the bees that they stung him and every one else they came across, and very nearly stung a cow to death at a distance of about a hundred yards from the apiary; and on another occasion a horse, still wet with sweat, trespassed too near a hive, with the result that the whole apiary was in an uproar, and some of my children and servants were stung, the chief victim being a Malay girl who used to apply quantities of scented pomatum to her hair, and who was severely stung on the head. Mr. Romanes continues thus: "Again, many instances might be quoted, such as that given by Gueringius, who allowed a species of wasp, native to Natal, to build in the doorposts of his house, and who observed that, although he often interfered with the nest, he was only once stung, and this by a young wasp; while no Kafir could venture to approach the door, much less to pass through it." It does not appear whether any white stranger was ever stung, and the only inference that can be reasonably drawn from the conduct of the wasps is that they disliked the odour of Kafirs, which, as is well known, is peculiarly disagreeable. If a particular Kafir had been in the habit of passing through the door, the wasps would probably have become accustomed to his scent in the same way as a swarm of bees, upon the testimony of Sir John Lubbock, became accustomed to the scent of eau-de-cologne repeatedly dropped at the entrance of their hive.

The Metamorphic Origin of Granite

As I had charge of the granite quarries in Mull during the five years ending 1875, and am still closely connected with them, I would like to say that the conclusions stated in the Duke of Argyll's letter in your issue of last week (p. 578) are beyond all question correct, and are the same as I formed from independent observation while I lived at the quarries.

In addition to the facts mentioned in the Duke's letter, I would say that the structure shown by the granite while decaying under atmospheric action and the cleavage which it shows in the quarry all may point to its having been a stratified rock at one time; and in several places on the shore of the Sound of Iona and in North Bay Quarry, patches of semi-metamorphosed schist are found in the granite. One very fine specimen is on the north side of Fionphort Bay.

The change from schist to granite on the north side of the peninsula of Ross, which the Duke speaks of as "obscured at the head of Loch Laigh," does, according to my observation, not take place there, but a little further west, in a bay between Loch Laigh and the inlet leading to Ardfenaig. The change can be traced foot by foot there most perfectly, and any number of specimens of it in all stages can be picked up on the beach.

Though, however, the metamorphic origin of the Mull granite is, in my opinion, beyond doubt, I think that the metamorphic agent has yet to be discovered. The most plausible hypothesis is that it was a superincumbent mass of trap, but an inspection of the very destructive influence of the trap dykes that we meet with in the quarries upon the granite about them makes this very unlikely to my mind. For some distance on each side of such dykes the granite is quite useless.

Helix pomatia

As *Helix pomatia* appears to be very partial in its distribution in this country, it may be worth while to record the fact that I have met with it on and near the chalk downs in the neighbourhood of Epsom, and on the chalk downs above the village of Hambledon, in South Bucks; while Mr. J. E. Harting states that it is not uncommon on the chalk hills in the vicinity of Reigate and Dorking, and in parts of Kent.

Forbes and Hanley, in their "History of British Mollusca," say "it is entirely confined to the southern counties, living chiefly on cretaceous soils"; but we learn from Mr. Gwyn Jeffreys (NATURE, vol. xxvii. p. 510) that it is abundant at Woodford, in Northamptonshire; and from Mr. Blomefield (NATURE, vol. xxvii. p. 553) that it occurs sparingly in Gloucestershire, neither of these counties being cretaceous.

With regard to its possible introduction into this country by the Romans, we gather from Venables' trustworthy work on the Isle of Wight that *Helix pomatia* has not been met with in the island, although it was occupied—and probably permanently—by that people; but *H. scalaris*, which, according to some malacologists is a monstrous form of this species, has been found there. Its absence from the Isle of Wight may be said to be somewhat remarkable, seeing that the species extends in the south at least as far as the borders of West Sussex, and that the other British chalk-frequenting *Helicidæ*, *H. caperata*, *H. ericetorum*, and *H. virgata*, are very abundant in the island. Either of two causes may account for its absence from this locality:—it may be a geologically recent importation from its original (?) centre in France, and has not yet succeeded in navigating the salt waters of the Solent; or its exceptionally large size may have proved its destruction in its exposed favourite haunts. The latter supposition is the more probable one, as it would account for its general rarity, and at the same time help to explain the prevalence in the same exposed haunts of the smaller *Helicidæ*.

The Zodiacal Light (?)

REFERRING to the sunset phenomena described by J. W. B., of Bath, in NATURE, vol. xxvii. p. 580, permit me to inform you that I also was an observer and was well aware from previous experience that it was not the zodiacal light, which, as seen in the evening from any latitude north of the tropics always inclines to the left, and, if seen in the morning, in the east, then to the right, whilst the phenomena in question appeared as a vertical column, of a warm tint, extending upwards to about 5° from where the sun had just set moving to the right, and descending with that luminary, continuing visible for about thirty minutes from the time I first noticed it immediately after the sun had gone down behind the low range of the Yorkshire Wolds, distant from my garden five or six miles in a north-west direction.

Having never before witnessed a similar phenomenon, although I have had for upwards of eleven years an uninterrupted view of the sunset region of the sky, and, except in midwinter, am nearly always at home at sunset, and on fine evenings in the garden, I was somewhat puzzled as to whether the cause was local and atmospheric or otherwise.

If your correspondent can refer to the "Heavens," by Guillemin, p. 86, 1st edition, or to Milner's "Gallery of Nature," 1st edition, p. 62, he will there see woodcut representa-

tions of the zodiacal light, or to "Chambers's Astronomy," 3rd edition, p. 92, where a short chapter is devoted to the subject.

Speaking from my own experience, the zodiacal light is best observed in this neighbourhood during the clear evenings of February or March, in the late twilight, and of course in the absence of moonlight.

On referring to my copy of the *Astronomical Register* for 1875, vol. xiii. p. 196, I find a letter from Mr. T. W. Backhouse in reply to a previous communication from Canon Beechey in the same volume, p. 174, describing what appears to have been a much finer display of this sunset phenomenon as seen by the rev. gentleman from Downham, Norfolk, than either your correspondent or myself witnessed.

Mr. Backhouse states: "It is purely an atmospheric phenomenon ascribed to the sun shining on particles of water or ice."

May I ask if the above explanation is an established fact or only a theory?

I shall be glad if you receive and can make room for the accounts of other observers, as I cannot think the appearance is a very common one—at least not in this neighbourhood.

Hull, April 24 WILLIAM LAWTON

REFERRING to the letters in your columns on this subject, I beg to forward two photographs of the sun, which show distinct horns of light on each side of the disk. They were taken—the sun high in the heavens at the time—some two months ago in a simple camera, without any special arrangement, except a rapid shutter, but the development was undertaken with some care, and arrested as soon as the light fleecy clouds around made their appearance. H. B. P.

Blackheath, April 27

[WE have received the photographs, which are certainly very remarkable if our correspondent can certify that the strange prolongations which appear on them are special to them, and not in any way dependent upon any possible reflection from the lenses employed.—ED.]

THE phenomenon described on pages 580 and 605, under the heading "The Zodiacal Light (?)" was that generally known as a "Sun Pillar." I send herewith an engraving of one seen from Sidmouth in 1871, full descriptions of which were given in the *Meteorological Magazine* for May, June, and July of that year.

Sun Pillar seen near Sidmouth, April 4, 1871.

I believe that it is merely a portion of a halo passing vertically through the sun; in the recent case, that portion of the halo which was *above* the sun was alone seen, sometimes the portion *below* it is seen alone, and occasionally both are visible, together with a parhelic circle (or parts of one), and then of course we have the rare phenomenon of the sun as the centre of a luminous cross. I have called this complete phenomenon of the solar cross rare, for I know of only three occasions of its being seen, and even these I have not verified in the originals, but those interested may search in *Hugenii Opuscula posthuma*, ii. 48, for the details of the phenomenon seen in Cassel in January, 1586, by Roth; and in the *Mém. de l'Acad. des Sciences* for 1693 and 1722, for descriptions by Cassini and Maléziec. G. J. SYMONS

62, Camden Square, N.W.

THE curious luminous projection after sunset on the 6th inst., noticed by several of your correspondents, was also seen for some time very soon after sunset in Herefordshire. Its shape was somewhat like a vertical pillar of soft, hazy, yellowish, luminous light, about the width of the solar disk, 10° in height above horizon, and finishing rather abruptly with a conical termination in a clear sky. R. P. GREG

Coles, Buntingford, Herts, April 29

ALLOW me to call the attention of such of your readers as are interested in the above phenomenon, to a communication from Mr. J. J. Murphy of Belfast, in your issue of July 13, 1876, and to another from myself, a fortnight later, describing a sun pillar seen in the north of Ireland on June 27, 1876. R. V. D.

Beragh, co. Tyrone, April 28

Mock Moons

THE mock moons mentioned in your last week's issue (p. 606), by Mr. Mott, were seen here. The circle subtended an angle of 50°. When first seen, a line drawn through the mock moons passed through the moon itself. At 11 p.m. such a line was 3° above the moon. At 1 a.m. the appearance was as at first. This change of level of the refracting cloud is what Mr. Mott alludes to when he says it "seemed to be unaccountably out of place." I was not aware that there was any fixed place for the brighter portions of the halo. SM.

Temple Observatory, Rugby

The Freshwater Medusæ

IT may interest some of your readers to know that the little freshwater Medusæ (*Limnocodium Sowerbii*), which appeared in the Victoria Regia Tank here on June 9, 1880, for the first time, again on June 12, 1881, and not at all during 1882, appeared again in the tank on Saturday morning, April 28, many of them being full grown individuals. The tank, which remains empty during the winter, was filled with water on March 8.

The Circles of a Triangle

CANNOT the method of "portmanteau" words be advantageously applied? I beg leave to suggest the following names: *circumcircle, incircle, excircle,* and *midcircle;* these are for speech, in print or writing they might appear C⊙, I⊙, E⊙, M⊙.

April 28 W. H. H. H.

Flight of Crows

IN watching crows as they fly overhead, I often think they are not flying straight forward, but have the line from head to tail at an angle of about fifteen degrees with the line of flight. Can this be corroborated? I do not like to trust my own observing powers in such a matter. JOSEPH JOHN MURPHY

Old Forge, Dunmurry, co. Antrim, April 24

METAMORPHIC ROCKS OF SCANDINAVIA AND SCOTLAND

MUCH interest attaches to the researches of the Swedish geologists among the older crystalline rocks of Scandinavia. In the year 1873 Mr. A. E. Törnebohm published an important paper in which he showed that in the high grounds of Sweden Lower Silurian rocks, with recognisable fossils, pass up conformably into a vast overlying series of quartzites, schists, and gneisses. These metamorphic rocks were divided by him into two groups—the Seve group, composed mainly of quartzites and schists, and the Köli group, consisting

largely of mica-schists and clay-slates. In another memoir just published he furnishes additional information regarding the succession of these rocks. The old or fundamental (Archæan) rocks composed of gneiss, granite, &c., are overlain by thick masses of reddish sandstones, followed by quartzites and limestones, over which come Augen-gneiss, hornblende-schist, mica-schist, &c. This order of sequence, which is shown in numerous natural sections, will be at once recognised as that which Murchison first showed to be the stratigraphical succession in the north-west of Scotland. It is interesting to find that the parallelism which was traced many years ago between the structure of the Highlands of Scotland and the uplands of Scandinavia continues to be confirmed by the more detailed surveys of recent years.

Prof. Math., U.S.N.

Washington, April 6

ANTHROPOLOGY[1]

I.

THE invitation to lecture on anthropology with which I have been honoured gives me freedom to speak both of the races of mankind zoologically, and also of the thoughts, arts, and habits which form their civilisation. It is on the development of civilisation that I especially wish to dwell, a subject of direct interest always and to all, and the more opportune now that the practical question of the instalment of a Museum of Civilisation in Oxford is under discussion. Still, man's bodily and mental history so act and interact on each other that it is well to carry on their study together. Both depend on the great principle of adaptive change, where rise in organisation gives fuller and freer existence, till "correspondence with the environment" fixes a more or less permanent state, or suppression or disuse brings on degeneration. These are processes systematised in the theories of development or evolution which have of late years become predominant, and which seek to account for the change of plants and animals on the earth by modified descent, and of mental and moral phenomena by modified sequence. There is a consideration I wish to bring prominently forward, as not having had the attention it deserves. It is that these processes of development, or evolution, or transformism were long ago recognised to no small extent by ethnologists. Thus Prichard, the leader of the monogenist school forty years ago, brought forward evidence for the derivation of the races of mankind from one original ancestral pair, whom he considered to have been negroes, whose descendants more or less varying by the operation of natural causes became modified or transformed into the various races adapted for life in the various climates of the earth. But this, so far as it goes, is the very theory of development or modified descent. Any ethnologist who argues on natural grounds "that all the races of man are descended from a single primitive stock," is an evolutionist within these limits; in fact these words are quoted not from Prichard or Quatrefages, but from Darwin. Within the last generation the science of man has had new evidence and argument brought within its range. The discovery that men were already making rude flint implements in the Quaternary period, when the contours of hill and valley were quite other than during the few thousand years known to chronology, has made a new scientific departure, placing primæval man in the hands of the geologists, who are now discussing whether he even existed in the yet more vastly remote Tertiary period. A yet greater move has been made by Darwin's systematic application of the principles of variation of breeds or races to account for the transitions between species or genera. How these have become transformed in the course of geological time is seen in Huxley's plate of the bones of the four-toed Orohippus, followed by the three-toed Miohippus and Hipparion, and this again by the horse of the present day. Zoologists thus enabled to reconstruct ideally the ancestry of the horse, are hopeful some day to discover likewise the fossil pedigree of the rider.

Thus it is plain why the new lines of biological research, whether into the general causes of variation in animals, or into the origin of the human species from a succession of lower mammalian forms, have not checked but stimulated the research which relates to man as man. Anthropologists do not feel as if their science had been plucked up by the roots and planted somewhere else; it is growing where it was, only cultivated higher than in old times. What substantial progress has been made of late years is well seen in the difficult department of craniology. That there really is something in the shape of a skull will be admitted when one compares the two before us on the table, types which illustrate an interesting point in the early history of our own country. The narrower skull belonged to one of that dolichocephalic Stone Age population whose remains were buried in the long-barrows on our downs. The broader skull belonged to one of the brachycephalic men of the later round-barrows. In the work of Greenwell and Rolleston will be found the anatomical comparison of these skull-types, and the evidence that the earlier tribes were not exterminated by the later

[1] Two lectures on "Anthropology," delivered on February 15 and 21 at the University Museum, Oxford, by E. B. Tylor, D.C.L., F.R.S.

invaders of the land, but that the two races lived and were buried together, and by intermarrying gave rise to a mixed population. What these early long-headed people were called, or what language they spoke, is still unknown. It is they to whom, on the strength of certain passages in classic authors, the name of Iberian has sometimes been given, and they have been identified with the Basques. But no absolute correspondence has been made out between them and any race past or present in Spain, so that Prof. Rolleston was wise in preferring to call the men of the English long-barrows by the local name of Silurians, and to rely on skulls for defining the type, and the burial-places for marking the state of civilisation, of an ancient race who thus take a well-marked place in the history of our land, but of whom we may possibly never learn much more.

The mixture of races which has gone on for ages in Europe makes European craniology a study of extreme difficulty, but to see its clearest results we must look to races long isolated and intermarrying till their skulls become almost uniform. How such a type will characterise a genuine race has been shown by Prof. Flower in describing the skulls from the burial caverns of the Kai Colo, the mountain people who appear to have been the original inhabitants of Fiji. These mountaineers, whose distinction it is to have had the narrowest skulls of any known race, are representatives of the frizz-haired blacks so widely spread in the island groups now called after them Melanesian. But the ordinary Fijian population, who have lately been incorporated in the British Empire, are not exactly Melanesians, nor are they Polynesians like the brown Samoans and Tongans of the islands to the eastward. It appears that these black and brown islanders have intermixed and become the joint parents of the present Fijian population. This is perfectly shown by their skulls, whose cephalic index of breadth (71) is intermediate between those of the two parent races, the ancient Melanesian mountaineers (66) and the Polynesians (83). Not only does the cephalic index of length and breadth follow this rule, but it proves true in the same way of the index of height, and of other measurements of jaw, eye, and nose, which almost absolutely follow the same rule of the mixed race between the two parent races. The gradation is so marked, that in the Fijian islands nearest the Polynesian islands the skull-measurements come nearest to the Polynesian type. It is I think the first time that anthropology has made so close an approach to mathematical accuracy in its inferences, and it must be admitted that when arithmetical rule thus finds its way into a descriptive science, the study is becoming serious. Let us now see what comparative philology has to say to this Fijian question. Every student who opens a Fijian grammar is apt to say, Here is a Polynesian language, like Maori or Tongan; the map shows in the names of the islands plain Polynesian words that a New Zealander would understand, such as *vanua* = land, *lima* = five; the Fijian not only has the familiar Polynesian *tabu* = sacred, but he can attach the Polynesian causative prefix *waka* to it and make the verb *wakatabu* = to tabu a thing or make it sacred. Yet this student, as he examines and analyses more deeply, is driven to admit that Fijian must not be catalogued among the Polynesian languages; indeed it seems as though the root and heart of it must be classed as Melanesian, belonging to the black not the brown race; nevertheless the black language has absorbed not only the words but the character of the brown language into an intimacy and depth of mixture hardly anywhere equalled. Prof. Max Müller, in the lectures which near a quarter of a century ago made a new era in the science of language in England, was careful to give the much-needed caution not to trust too much to language in settling questions of race. Here, however, is an example how language, in cases when it is possible to get its bearing clearly into view, may tell its story in perfect accordance with anatomy. The blended parentage of the Fijians is heard in their speech as it is seen in their faces.

Not less important as a distinctive mark of race is the hair. A single hair now enables the anthropologist to judge in what division of the human species he will class its owner; there is no mistaking a Chinese for a European, or either for an African. The cross-section of this single hair, examined microscopically by Pruner's method, shows it circular, or oval, or reniform; its follicle-curvature may be estimated by the average diameter of the curls as proposed by Moseley; its colouring matter may be estimated by Sorby's method. There has been even a systematic classification of man published by Dr. W. Müller, of the Novara Expedition, which is primarily arranged according to hair, in straight-haired races, curly-haired races, &c., with a secondary division according to language. Though we cannot regard such a system as good, the wonder is that it should answer so well as it does; indeed nothing could prove more clearly how real race-distinctions are, that a single bodily character should form a basis for rationally mapping out the divisions of mankind.

It is now well understood that the causes of race-colour are not so simple as Hippocrates thought when he described the nomad Scythians as burned tawny by the cold. But the study of anthropologists is still to notice the characters which mark off the white, yellow, brown, and black races, and to connect therewith the effects of climate and mode of life. The analogy of fair or blond skin to partial albinism is striking, and possibly points to some similarity of cause. A book has even been written by Dr. Poesche to explain thus the formation of the white race. The fair whites, according to this author, are semi-albinos, whose ancestors were once a browner race in Northern Asia, but turned fair in the swampy regions of the Dneiper, where men and beasts grow light in colour, horses grey, the leaves of the trees pale, and all nature dull and colourless. Such imaginative speculation is an example to be avoided by anthropologists, and yet the resemblance of blond to semi-albino skin is one which when worked out by careful observation will doubtless lead to discovery. A yet more striking case of the morbid appearance of race-character is seen in "bronzed skin," a symptom of "Addison's disease." Here the resemblance to mulatto complexion is so marked that in the reports of cases it is quite a regular thing for the physician to mention that he asked the patient if he was of negro blood. Even that well-known negro feature, the comparatively light tint of palms and soles, was there, though there was wanting one of the points which anthropologists look to when they suspect negro ancestry, namely, the yellowness of what we characteristically call the "white" of the eye. It is not however on merely superficial comparison that this analogy depends. Anthropologists unfortunately do not always hear of medical work bearing on their studies, and it is but lately that I learnt from Dr. Wilson Fox that an interesting microscopic section of "bronzed skin" was published years ago by Mr. Hutchinson in the *Pathological Transactions*. All who compare this with Kölliker's section of normal negro skin must admit the extraordinary similarity of coloration, in the manner in which the deep brown pigment cells and grains line the surface of the papillæ of the dermis or true skin. I shall not be charged with propounding here a theory that black men are white men thus transformed, for, indeed, one incident of the obscure disease in question is that the patient always dies. The importance of the comparison lies in its bridging over the physiological differences of race, by showing that morbid action may bring about in one race results more or less analogous to the normal type in another.

The differences in race-characters among mankind are

far better known than are the causes which bring them about. Yet it would be too much to say that we do not know how to alter the type of a race. For instance, stature is one point of race-type, and we know by actual experience that if a population of the Yorkshire dales is brought in to live in factory towns, in two generations they are found to be $1\frac{1}{2}$ inch lower in average stature than their countrybred kinsfolk. Indeed, it appears from Beddoe's careful statistics that the stature of the London population is gradually lessening. The great means of change of race-type is acclimatisation Dr. Acland has here called attention to the interesting problem presented by the tribes of "unhealthy districts" in India, who live where tribes allied to them in race and language cannot exist, nor can they themselves go back, without falling sick, to the plains whence their ancestors came. That this acclimatisation affects the secretions and hue of skin is certain, but this topic is one on which only a pathologist can speak with any authority. If, however, we look at the map of the world, it is as evident to us as it was to Hippocrates that race depends in some measure on climate and mode of life. The leading fact is the lie of the negro type along the equator, as contrasted with the xanthous or blond type in the northern temperate zone. The permanence of the races of mankind, such as the Egyptian, which the polygenist school interpreted as evidence that it was a species by itself, is better explained in Draper's words that "its durability arises from its perfect correspondence with its environment." It is only when moved into different conditions that a race has to change into harmony with these new conditions.

Turning now from the development of races to the development of their civilisation, the task is made easy by the help of evidence geological in its character. The presence of stone implements in every part of the world proves that they were once used there, and that the races using them had no metal. But now stone implements are distinguished into the ruder Palæolithic and the more finished Neolithic. The ruder, discovered in gravels of great antiquity with the remains of the mammoth and other prehistoric animals in Europe, must therefore be the older, but this also seems to be evident from their very nature. If men with bronze weapons had no more bronze, they might very likely fall back on the best substitute they could make, the hard, ground stone celt; but it seems against all reason that those who knew how to grind a hatchet on a whetstone should have lost that simple if laborious art. Thus culture confirms what geology teaches, that the rude stage of man's history to which the rude implement belongs is also the earlier stage, and the higher polished implement comes later. It comes on indeed into modern times, for the general extinction of the Stone Age in Australia or America only dates from this century, and even at this day in Australia the traveller learns from the blackfellow how the rude chipped axe-flake is to be gummed to the helve, or the white hunter sits down in California to be shown how to chip out the neat obsidian arrowhead with the point of deerhorn. In a few ages after metal has come in, the new people forgets that the old people ever used such things. Thus it comes to pass that, across the world from Iceland to Japan, stone hatchets and arrowheads dug up in the ground are supposed to be the material weapons hurled or shot from the sky, whose flight is seen in the lightning-flash Such "thunderbolts" have for ages been valued for magical power, especially the appropriate uses of guarding against fire and inflammatory disease; Pythagoras was purified with a thunderbolt, and stone arrowheads form the centre-pieces of some of the most beautiful of Etruscan gold necklaces. Even a bronze implement may be taken for a thunderbolt by those who have forgotten its nature; the bronze celt here produced was dug up in Wiltshire, where the lightning had struck an oak, and it has since for many years been the magical thunderbolt of a west country hamlet.

Even where the old use dwindles and changes, survival in altered shape may keep on the old ideas: our own life is full of survivals. In ceremonial processions we still see the javelins and halberds belonging to war before gunpowder, and though the mace no longer smashes helmets, it remains as an emblem of power and dignity. Our books are ornamented with gilt lines which once represented the real cross-binding; as in perhaps the most modern of survivals, where the tape which bound the registered letter has dwindled to blue cross-lines printed on the envelope. Language is full of such records of the past; as when one hears people declare they do not care a *groat*, a *doit*, or a *rap*, when they would not recognise if they saw them these old-fashioned varieties of small change. Thus what with the lasting on of old things among outlying peoples, and what with the survival of them among the civilised world, the thread of connection is by no means lost from remotest times. For my own part, when I look at the utter likeness of the working processes of the mind among the races most different in skin, and when I see the resemblance of rude ideas and customs throughout the inhabited world, I cannot but think that much of the thought and habit of mankind not only goes back to the remote Palæolithic age, but that it may be older than the divisions of race which separate us from the Chinese or the Negro. Let me offer examples of a mental state yet surviving which may have its origin in the very childhood of mankind. Uneducated men, from the savage to the peasant, remain more or less in that childlike state of mind where the distinction between dreams and real events is not yet perfectly made; dreams seem to be visits from phantom souls of others coming to the sleeper, or excursions of his own phantom or soul away from his body. The state of primitive thought in which psychology thus grows out of the phenomena of dreams has perhaps never been better displayed than in a recent account by Mr Im Thurn in the *Journal of the Anthropological Institute* of his Indian boatmen in British Guiana. One morning a young Macusi was so enraged against him that he refused to stir, declaring that his master, without consideration for his weak health, had taken him out in the night and made him drag the canoe up a series of cataracts. Nothing would persuade him that it was only a dream, and it was long before he was sufficiently pacified to throw himself sullenly into the bottom of the canoe. Food was scarce, and such dreams in consequence frequent, so that morning after morning the Indians were complaining that some man (whom they named) had visited their hammocks in the night, and beaten or otherwise maltreated them. In the middle of one night Mr. Im Thurn was awakened by his headman, an Arawak named Sam, who addressed him in these bewildering words: "George speak me very bad, boss; you cut his bits." On explanation, it proved that Sam had dreamt that George, one of the men under him, had spoken impudently to him, and had come at once to his master to demand that the culprit should be punished by cutting so many bits (*i.e.* fourpenny pieces) off his wages.

This instance of mental rudeness comes from among tribes who are hardly above the savage level, but not less remarkable survivals of primitive thought may be found among peasants. Thus that most archaic practice, the burial of objects for the use of the dead in the future life, is still continued in Europe. One of the latest instances comes from the village of Lückendorf in Saxony, where the schoolmaster, Herr Kühne, describes how when a mother dies in childbirth, they bury in the coffin all she wants for the child gone before—the little earthen pipkin and spoon, and a supply of groats, the baby-clothes, with needle and thread, thimble and scissors to mend them, and even a tiny model of the mangle,

because it is too large to bury. This is in a Wendish district, where prehistoric customs are more obstinately kept up than in purely German parts. Nothing could more perfectly illustrate the early animistic belief in the ghost turning to ghostly use the phantoms of objects laid for it in the grave. Thus we have, parallel with the rude material life of the Stone Age, traces of a corresponding intellectual rudeness, belonging to ages when men had not learnt to distinguish dreams from events, or to realise the meaning of death.

The problem of the order in which the races of men were formed and attained such culture as they have is obscure and perplexed enough, but it has some illuminating facts. The method by which an anthropologist judges of the centre of civilisation of a race is much the same as that of the botanist who looks for the district where a widespread cultivated plant is found wild, as the potato is in Chile, which accordingly he takes to be at or near the centre of distribution; only he has to guard against the possibility of the wild plant being only a cultivated variety run wild. Let us now apply this method to the geography of the Negro race. The negro or negroid spread over the African continent have never risen high in civilisation, scarcely of themselves getting beyond the barbaric stage. But on the other hand they are never very low; they are tillers of the soil, herdsmen, iron-workers, and no negroid tribe has been found in a clearly primitive savage state. The Bushmen, belonging to an allied variety of man, are outcasts and savages by degradation. If however we look along the map of the world for the eastern branch of the black race, we find in the Andaman Islands and in New Guinea and other islands Negro types more or less assimilated to the African, but living at lower stages of culture such as are possible in the rank forest-lands of the equator. In these two districts are found the only well-authenticated accounts of tribes with no knowledge of any means of making fire. The Andamanese have not the fire drill or any such fire-making instrument, but carry burning brands about with them, and if by any chance they lost their fire, they could kindle it anew at their volcanoes. In an outlying district of New Guinea, Mikluho-Maclay has found a Papuan tribe who only carry fire-brands, and do not know the fire-drill of other districts. This indicates very low culture, whether they are representatives of an originally fireless state, or whether by mere inertness they have disused and forgotten so useful an art as firemaking. In these regions is perhaps the Negro centre whence, rising to a somewhat higher level of culture, the western branch spread over Africa. Let us now look at the white men from this point of view. There may be remains of Stone Age Whites, but there are no certain remains of White savages of a low order. We may well doubt if there ever were any White savages; it is more likely that the White men were developed late in the race-history of the world from ancestors already far on in civilisation; in fact, that this civilisation with its improved supply of food, its better housing and clothing, its higher intellectuality, was one main factor in the development of the White type. Here, however, it must be remembered that there is not a White race in the sense in which there is a Carib race or an Andaman race. It includes several race-types, and even the same language, such as English or German, may be spoken by men as blond as Danes or as dark as Sicilians. The fair-haired Scandinavian type has something of the definiteness of a true race; but as one travels south there appear, not well-defined sub-races, but darkening gradations of bewildering complexity. The most reasonable attempt to solve this intricate problem is Prof. Huxley's view that the White race is made up of fair-whites of the Northern or Scandinavian type, and dark-whites who are the result of ages of mixture between the fair-whites and the darker nations, though it is perhaps hardly prudent to limit these dark ancestors to one variety as he does. If now we cannot trace the White man down to the low level or primitive savagery, neither can we assign to him the great upward movement by which the barbarian passed into civilisation. It is not to the Aryan of Persia nor to the Semite of Syria that the art of writing belongs which brought on the new era of culture. The Egyptian whose hieroglyphics may be traced passing from picture into alphabet had his race-allies in people of North Africa, especially the Berbers of the north coast, people whom no elasticity of ethnological system would bring into the white race. Of the race-type of the old Babylonians, who shaped likewise rude pictures into wedge-phonetic signs, we know but little as yet; at any rate their speech was not Aryan, and the comparisons of Lenormant and Sayce have given some ground for connecting it with the Turanian language, belonging to a group of nations of whom one, the Chinese, had in remote antiquity worked out a civilisation of which the development of an imperfect phonetic writing formed part. If the great middle move in culture was made, not by any branch of the white race, but by races now represented by the Egyptian and the Chinese, it is not less clear that these nations came to the limit of their developing power. The white races had in remote antiquity risen high in barbaric culture when their contact with the darker nations who invented writing opened to them new intellectual paths. The Greeks found in the ancient Egyptian theology the gods of the four elements, but they transferred this thought from theology to philosophy, and developed from it the theory of elements and atoms which is the basis of modern chemistry. They found the Babylonians building terraced temples to the seven planets in the order of their periods, and this conception again they transferred from religion to science, founding on it the doctrine of planet-spheres which grew into mathematical astronomy. It may moderate our somewhat overweening estimate of our powers to remember that the white races cannot claim to be the original creators of literature and science, but from remote antiquity they began to show the combined power of acquiring and developing culture which has made them dominant among mankind.

(*To be continued.*)

PROFESSOR ARTHUR ROCHE

M. ARTHUR ROCHE, Professor of Mathematics and Astronomy at the Lycée of Montpellier, died at that town on April 18 last, in the sixty-third year of his age. M. Roche's name is most intimately associated with researches on the figures of planets and comets, and the cosmogonic theory of Laplace. In the report on the labours of Roche made to the Academy of Sciences last week by M. F. Tisserand, his memoirs were thus classified:—1. Various memoirs on the equilibrium of a homogeneous fluid mass subjected to certain conditions. These had special reference to the beautiful researches of mathematicians on the equilibrium of a homogeneous fluid mass, animated by a movement of rotation around its axis, the molecules of which are attracted according to the law of Newton. M. Roche proposed to determine the figure of equilibrium by taking into account a new force—the attraction exerted by a centre situated at a great distance. M. Roche worked out this idea with great success, applying it specially to the moon, to the satellites of Jupiter and Saturn, to comets, and generally to the evolution of the solar system. 2. Memoirs on the physical constitution of the terrestrial globe, in which he came to the conclusion that the density at the centre is nearly double the mean density. 3. Memoirs on the internal condition of the globe, in which M. Roche was led to pronounce against the complete fluidity of the interior. 4. Various memoirs on the figures of comets.

5. Essay on the constitution of the solar system, in which M. Roche attempted to develop the beautiful cosmogonic theory of Laplace, giving precision to certain points and modifying it in others. M. Roche was a Corresponding Member of the Academy of Sciences in the Section of Astronomy, and had been nominated as a candidate for the place vacant by the death of M. Liouville.

THE LATE MR. W. A. FORBES

MR. WILLIAM ALEXANDER FORBES, Fellow of St. John's College, Cambridge, Prosector to the Zoological Society of London, and Lecturer on Comparative Anatomy to Charing Cross Hospital, whose untimely death on the Niger we announced last week, was born at Cheltenham on June 24, 1855, the second son of Mr. J. S. Forbes, the well-known railway director. He was educated at Kensington School and Winchester College, which he entered at the early age of eleven. On leaving Winchester in 1872, Forbes passed a year at Aix-la-Chapelle studying German, and then became a student of the University of Edinburgh, where he pursued the regular medical course, paying special attention to zoology and botany, and commencing collections of insects and plants. In 1875 Forbes transferred his residence to London, and entered himself as a student of London University with the idea of taking a medical degree in the metropolis. Here he became quickly intimate with other zoologists, who were very soon attracted by the astounding general knowledge of zoology and the acute intelligence of one so young. By the advice of the late Prof. Garrod and other friends Mr. Forbes was induced in October, 1876, to leave London and to become an undergraduate of St. John's College, Cambridge, where he was subsequently elected Scholar, and took his B.A. degree with a First Class in the Natural Sciences Tripos in 1879. The post of Prosector to the Zoological Society of London having become vacant in October, 1879, by the lamented death of Prof. Garrod, Mr. Forbes was appointed (*omnium consensu*) to that office in the January following. Indeed he had been designated by Garrod on his deathbed as his most obvious and proper successor, and had been appointed his literary executor.

Mr. Forbes entered upon the duties of his office with characteristic energy, and during the three following sessions of the Zoological Society brought before the scientific meetings a series of most interesting and valuable communications derived from his studies of the animals that came under his examination. He had a happy knack of putting forward abstruse points of anatomy in an understandable form, and especially directed himself to the muscular structure and voice-organs of birds, in continuation of the researches of his predecessor Garrod on the same subjects. In the summer of 1880 Mr. Forbes made a short excursion to the forests of Pernambuco, Brazil, of which he published an account in the *Ibis* for 1881, and in the following year passed his holiday in the United States, in order to make the acquaintance of his American brethren in science and their collections. In July, 1882, he left England on what promised to be a splendid opportunity of visiting the eastern tropics with every advantage and without much risk. Detained at Shonga—a station some 400 miles up the Niger below Rebba—by the breaking down of his communications, Mr. Forbes fell a victim to dysentery on January 14 last, thus adding another name to the long list of martyrs of science in that deservedly dreaded climate.

Mr. Forbes's published works consist chiefly of papers in the *Proceedings of the Zoological Society* and the *Ibis*, altogether about sixty in number. He was editor of the memorial volume of collected scientific papers of his predecessor Garrod, and just before he left England in July last had finished the last sheets of an excellent memoir on the anatomy of the petrels—since published in the "Zoology of the *Challenger* Expedition." This piece of work was originally undertaken by Garrod, but had been left almost uncommenced at the decease of the latter.

Of Forbes's private qualities as a most efficient and ready fellow-worker, a most charming companion and a most sincere friend, the writer is able to testify, not only from personal experience, but also from the universal regret expressed at the unhappy end of so promising a naturalist. P. L. S.

RECENT INFLUENCE-MACHINES

SEVERAL modified types of influence-machine have recently been brought before the public, and as they are both cheaper and more efficient than the older forms of Töpler, Holtz, and Bertsch, will probably find general acceptance. Of the newer forms, those of Voss and of Wimshurst are illustrated in the accompanying cuts.

In the Voss machine, which may be regarded as a modified Töpler machine, there are two disks of varnished glass, one stationary, the other rotating in front of it on an axis which passes through a central hole through the fixed disk. A pair of pulleys with a strap provide the rapid movement necessary. At the back of the fixed disk are fixed two armatures or inductors of varnished paper,

FIG. 1.—Voss's Influence-Machine.

with a narrower central band of tinfoil. These armatures are connected on the right and left respectively with two metal clamps which nip on to the edge of the disk and turn round in front of the front plate, each being provided at this part with a little metallic brush. Upon the front of the rotating plate are fastened six or eight metal buttons at equal intervals. These buttons are touched as they rotate by the metallic brushes. Nearly perpendicular, and in front of the front disk, is a brass rod, which need not be insulated, also furnished with spikes at each end, and with a little metallic brush to touch the buttons of the rotating plate. The action of the machine is as follows:—If a small charge of electricity—say a positive charge—be imparted to one armature—say that on the left—the buttons as they move past will be acted on inductively, and if, while thus under the inductive influence of the positive charge, they are momentarily touched by an uninsulated conductor, they will pass on electrified with a charge of the opposite sign. If the front plate rotates in the clockwise direction, each button as it moves through its highest position towards the right will thus acquire a small negative charge which will be given up on arriving at the right side, the projecting arm conveying the charge to the armature at the back. But as the button passes on downwards it will be influenced inductively by the armature behind it, and when touched by the lower end of the vertical conductor, will assume a positive electrification.

On arriving at the left side it will therefore give up a small positive charge to the left armature, thus charging it more highly than before. Every button as it goes round thus conveys the charges induced in it to the appropriate armatures, and exalts their charge. A very few turns given to the handle suffice to charge those armatures to their fullest extent, so that they begin to discharge pale sparks over the disks. But now begins another action. From right to left in front of the front disk lies an insulating bar of ebonite, holding at each end another brass comb, each connected by a crossbar of brass to the knob of a small Leyden jar. As the charges in the armature rise they act again upon these conductors fixed in front of them, and charge the jars, one positively, the other negatively. A pair of dischargers with ebonite handles serve to discharge the jars when full, and with every turn of the winch, when the knobs of the dischargers are separated by a few centimetres' distance a torrent of sparks is generated. If the machine is kept free from damp and dust, no initial charge is necessary, as the slight friction of the brushes suffices to give and sustain the requisite preliminary electrification.

Wimshurst's influence-machine is even simpler, and if anything, more efficient. It is the result of a long experimental research carried out with great care and skill by Mr. J. Wimshurst, who is well known as an accomplished amateur electrician. The latest of the many combinations which Mr. Wimshurst has designed is depicted in Fig. 2. It consists of two disks of common window glass mounted upon a common spindle, and provided with driving gear by which an equal speed is given to each, but in opposite directions. Each disk (about fourteen inches in diameter in the smallest size) is well varnished with shellac varnish, and carries twelve narrow strips of thin sheet metal cemented at regular intervals apart. In front, at about 45°, is fixed a diagonal conductor armed at each end with a small brush of metallic bristles, which touch the metal strips as they rotate. At the back a similar diagonal conductor is fixed, exactly at right angles to that in front. Right and left are two upright pillars of glass or ebonite which carry each a pair of metallic combs, and serve also to support the dischargers which are carried in an arch over the disks. It appears that in this machine the metal strips affixed to the plates act both as inductors and as carriers. Suppose, for example, that the front plate is rotating clockwise, and the back plate counter-clockwise. If the metal strips descending from the summit on the left on the back disk are charged positively, the metal strips ascending on the front disk from the left will, as they pass under the momentary touch of the brush, acquire a negative charge. As these negatively charged strips of the front plate advance towards the right they will come to a point where they are opposite the upper end of the hinder diagonal conductor, and here, whilst still acting as carriers to bring the negative charge round to the right side, they will act as inductors, and will influence the strips of the back disk, which will, as they are in turn touched by the hinder brush, acquire positive charges. The strips on the front disk will therefore constantly carry a negative charge as they move over the top from left to right, and those of the back disk will carry a positive charge from right to left. In the lower halves of their respective rotations the inverse of these actions will hold good, the front carriers conveying positive charges from right to left, the back ones conveying negative charges from left to right. The result will of course be that the two main conductors on the left and right will become respectively positively and negatively charged. Theoretically, a small initial charge must be imparted to some one or more of the carriers or to one of the two main conductors. Practically, if dry and free from dust, the machine excites itself, and after a couple of turns

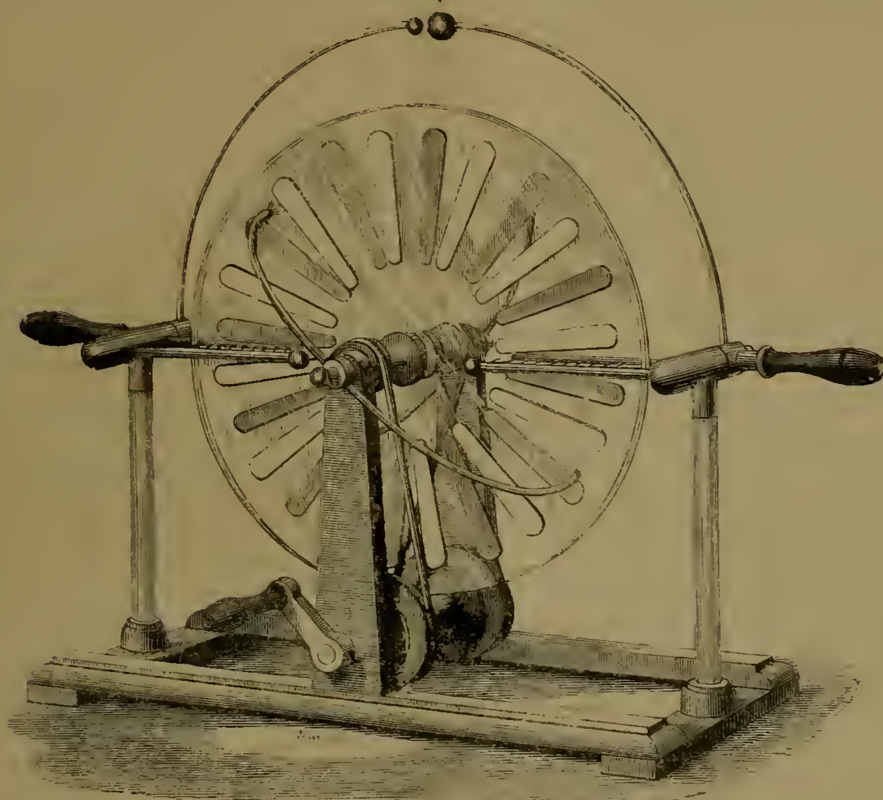

Fig. 2.—Wimshurst's Influence-Machine.

have been given to the handle, discharges sparks freely. If the two main conductors are respectively joined to the inner and outer coatings of a large Leyden jar, the discharges take place with short, loud sparks of great brilliancy. If from any cause the machine does not at once charge itself, a gentle rub with a silk handkerchief on either of the ebonite pillars will suffice to provide the requisite stimulus. The Wimshurst machine appears to be less liable than any other influence-machine to have the polarity of its charge reversed. It serves admirably for the production of the electric shadows discovered by Holtz and Righi. Mr. Wimshurst is much to be congratulated on the service he has rendered to experimental science in devising so useful and efficient an instrument.

THE ZENI NARRATIVE[1]

THERE is no greater puzzle in geographical literature than the so-called "Zeni narrative," which was published at Venice in 1558 by Francesco Marcolini, and claimed to be an authentic compilation by Nicolo Zeno of letters, in the possession of his family, which had been written at the close of the fourteenth century by two of his ancestors, the brothers Antonio and Nicolo Zeno, describing their adventures in the far north.

The story told by Nicolo Zeno was that when a boy he had found these letters in his father's palace, together with a map illustrating the travels of the Zeni brothers, and not knowing their value had torn many of them up. When he grew older he had however learnt to appreciate their true character, for like the rest of his family, one of the most illustrious in Venice, he was an accomplished scholar, and well acquainted with the results of geographical research. And collecting together all the letters that had escaped destruction, he compiled his narrative, and made a copy of the map, supplying from his own knowledge, and his interpretation of the travels of his ancestors, such names and other details as had become illegible from the then half-rotten condition of the original chart.

Ruscelli in 1561, and Moletius, one of the editors of Ramusio, in 1562, followed by the Venetian geographers generally, believed in the authenticity of the Zeni travels, as told by Nicolo the younger, who, as a Member of the Council of Ten, occupied one of the highest posts in the Republic, and was esteemed as a liberal patron of learning. But in other countries doubts were entertained in regard to the truth of the narrative, while in some quarters there arose an utterly untenable notion, that the book had been compiled with the object of securing to Venice the honour of having discovered the New World before Columbus set foot on it. In 1595 the Flemish geographer, G. Mercator, appeared as the first among many northern writers worthy of respect who refused to see in the story told by Nicolo Zeno anything more than a clever forgery. One of the latest, and probably the most formidable, of these detractors, was Admiral Zahrtmann, late Hydrographer to the Danish Admiralty. As an experienced seaman, an accomplished geographer, and a Dane well versed in the maritime history of the Danish Colonies with which he had long been intimately acquainted, he was eminently qualified to judge of the accuracy of a narrative, which professed to describe a voyage among islands and to regions, which the friends and foes of Zeno are alike agreed in believing we must recognise as the Faroe Isles, Iceland, and the eastern shores of Greenland. The substance of his careful analysis of the Zeni narrative, and of the map which accompanied it, was communicated in 1836 to the London Geographical Society, in the fifth volume of whose *Journal* it was subsequently published. And there is no doubt that notwithstanding the evidence that had been advanced in favour of the Zeni voyages by Hakluyt in 1600, and still more emphatically a century ago by Capt. Cook's companion, George Forster, English geographers allowed themselves to be powerfully influenced by the opinions of Zahrtmann. In our day, however, the tide of public favour has changed both abroad and in England. And in addition to the uncompromising testimony to the *bonâ fide* character and the general accuracy of the Zeno story, borne by Mr. R. H. Major in his edition for the Hakluyt Society, in 1873, of the "Voyages of the Zeni," and by M. G. Gravier in his "Découverte de l'Amérique par les Normands au 10ème Siècle," 1874, there is now the all-powerful evidence of Baron von Nordenskjöld to be adduced as corroborative, and seemingly conclusive, proof of the genuineness of this mysterious, and long-questioned story of early Venetian adventure in the northern seas.

While engaged in drawing up a history of north-eastern exploration for his "Voyage of the *Vega*," Nordenskjöld's attention was directed to the story of the Zeni voyages, of which he gives a Swedish translation in the number before us of the *Studier och Forskningar*, together with the result of his analysis of the narrative, and his comparison of the Zeno map with all the printed and manuscript maps known at the time of Marcolini's publication in 1558. Among the numerous interesting conclusions at which he has arrived, special attention is due to the following:—(1) That the general accuracy of the descriptions, for which there was no other known source, proves that the Zeni brothers must have been personally acquainted with the Faroe group and the other islands described in the narrative, as well as with the eastern shores of Greenland; and (2) that, considering the nature of the details given of the mode of life followed by the savages in regions lying in the north-west of the Atlantic, which are now known to us as Newfoundland, Canada, and the United States, but of which Europeans had no correct information until the colonisation of those lands in the seventeenth and eighteenth centuries, there is every reason to believe that the Venetian travellers conversed, as they assert, with persons who had visited these districts of the New World. Further, Baron von Nordenskjöld is of opinion that in the descriptions given by the Zeni's informants of the civilised communities, which they met with during their prolonged wanderings in these unknown western lands, we have evidence of the influence and persistence up to the close of the fourteenth century, when the Zeni are assumed to have been in the north, of the earlier Scandinavian colonies, which undoubtedly existed in the New World in the tenth and eleventh centuries.

The author shows that in the middle of the sixteenth century there were three maps in use, of the north and of the north-west, which, in addition to the Zeno map, had all been derived from northern sources, preceding the date of the discovery of America by Columbus. Of these the most important is a manuscript map, with descriptions of Northern Europe and of neighbouring lands, bearing the date of 1427, on which the Scandinavian countries are for the first time set down with anything like accuracy, and a considerable part of America is delineated. Our knowledge of this important pre-Columbian chart is entirely due to Baron von Nordenskjöld, who discovered it in a manuscript copy of Ptolemy's "Cosmographia," preserved in the Town Library of Nancy, of which he was permitted to make a facsimile, and to give a photographic copy in his *Studier och Forskningar*.

The value of this curious record of the geographical knowledge possessed in the early part of the fifteenth century of Scandinavia, and the adjoining seas, is increased by the fact that the map was laid down by a native of the Danish Island of Fyen, known as Claudius Clavus, or Cimbricus, who undertook the task for and

[1] "Studier och Forskningar, Föranledda af Mina Resor i Höga Norden; Ett Populärt Vetenskapligt Bihang til Vegas Färd kring Asien og Europa." A. E. Nordenskjöld. Häft 1. (Stockholm, 1883.)

at the instigation of the learned Cardinal, Gulielmus Filiastrus. Claudius' map, which is brightly coloured, and well supplied with the names and geographical determinations of places, ends at 74° N. lat., and begins at 55° N. lat., in which meridian a line is drawn through England, Holsatia (Holstein), and Pomerania, thus taking in the whole of the Baltic, whose islands and shores from the then Danish province of Halland, in Scandinavia, to the Gulf of Finland, are laid down with a fair amount of accuracy. In the far west we see Grönlandia, while on the shores of the Arctic Sea, named here "tenebrosum mare," we have at the very north of Scandinavia "Engrönuelandi," which would appear to have been an old designation of part of Finmark, and possibly the region from which Grönland derived its name.

In all respects the chart drawn by C. Clavus in 1427 is so far superior to the Donis map, printed at Ulm in 1482, which had formed the basis of Bordone's, and many other later maps, that, as Nordenskjöld points out, it must have been based on independent sources derived from the actual experience of seafaring observers. As, moreover, the Zeno map corresponds far more closely with the Clavus than with the Donis chart, with whose errors of position and distortions of outline it has little or nothing in common, there is not the slightest ground for asserting that the Benedictine monk, Nicolaus Donis, whose atlas is a mere copy of drawings to be found in the mediæval manuscripts of Ptolemy, was the authority from whom the younger Zeno derived his acquaintance with the far north, in which he included East Greenland and North-West America. We have no space to enter more fully into the interesting details with which Baron von Nordenskjöld supports his argument in favour of the authenticity of the Zeni narrative. But in conclusion we must draw attention to the success and ingenuity with which he has shown, that the often-sought-for and much-talked-of manuscript map of the north, which Admiral Zahrtmann saw in the University Library at Copenhagen, and declared to be the undoubted original from which Zeno's map had been derived, was simply a copy of Donis's chart. This fact he has so conclusively established, that henceforth Zahrtmann's charge against Zeno the younger must be considered to have lost one of its strongest supports; while future commentators on the Zeni voyages need no longer scour the libraries of Northern Europe in quest of a phantom map, whose disappearance soon after it had been seen by Zahrtmann has largely contributed to the tardy solution of the Zeno mystery.

NOTES

THE following awards will be made at the anniversary meeting of the Royal Geographical Society on the 28th inst.:—Founder's Medal to Sir Joseph Dalton Hooker, F.R.S., for his eminent services to scientific geography, extending through a long series of years and over a large portion of the globe, while engaged in voyages in the Antarctic and Australian Seas, and journeys in India and the Himalaya, in Morocco, and in the United States of America; and more especially for his long-continued researches in botanical geography, which have thrown light on the form of the land in prehistoric times, and on the causes of the present distribution of the various forms of vegetable life on the earth. Patron's Medal to E. Colborne Baber, Chinese Secretary of Legation, Peking, in recognition of the great value of his scientific work, chiefly geographical, during many exploratory journeys in the interior of China; and for his reports of these journeys, drawn up with admirable skill, accuracy, and completeness, which he presented to the Society, and which have been published, together with route maps engraved from his own finished drawings, in the first part of the "Supplementary Papers." The Murchison Grant for 1883 to Wm. Deans Cowan for his extensive surveys in the Tanala, Betsileo, and Bara provinces of Central Madagascar, an account of which was read by him to the Society in June, 1882, and published in the September number of the *Proceedings* of the same year; also as an encouragement to him in the new journey of exploration he is about to undertake in Western Madagascar. The Back Grant for 1883 to the Abbé Petitot for his geographical and ethnographical researches in the region of the great lakes of the Arctic basin, between Great Slave Lake and the Polar Sea, and his map of the basin of the Mackenzie. The Cuthbert Peek Grant for 1883 to F. C. Selous in acknowledgment of the value of his geographical researches in South Central Africa, including a journey in 1877 through the Manica country, north of the Zambesi, an examination of the hydrographical system of the Chobe, and two journeys by previously untrodden routes through Mashonaland, carefully prepared maps of which he communicated to the Society; also as an encouragement to him in the further researches in geography and natural history he has undertaken in the same region. The following will be elected as honorary corresponding members: Duca di Sermoneta (Prince Teano), president of the Italian Geographical Society, and of the International Geographical Congress at Venice, 1881; Dr. Schweinfurth, the eminent African traveller, now resident at Cairo; Edwin R. Heath, M.D., the explorer of the Beni River, South America, now residing at Wyandotte, Kansas, United States.

THE annual *soirée* of the Royal Society was held on the 25th ult. in the absence of the President, on account of indisposition. Among the recent scientific work illustrated was a photograph of the nebula in Orion, exhibited by Mr. A. A. Common, which is certainly one of the most interesting astronomical photographs which has ever been taken. We may also mention an interesting exhibit by Mr. W. Galloway, exemplifying the effects of coal-dust in colliery explosions, and "The Firedamp Cap," a phenomenon seen in mines. The only other exhibit of real general interest were some garlands from the tombs of Rameses II. and other kings, whose mummies were recently found at Thebes. Many of our readers have doubtless seen them in Egypt at the famous Boolak Museum, but those who have not done so must thank Dr. Schweinfurth for sending them over to Sir Joseph Hooker, and Sir Joseph Hooker for exhibiting them. These garlands are chiefly formed of leaves of *Mimusops Schimperi*, and petals of *Nymphœa cœrulea* and Lotus sewn together with fibres of date-leaf; others of the leaves of *Salix safraf*, with pods and flowers of *Acacia Nilotica*, *Sesbania Egyptiaca*, and *Carthamus tinctorius*, and petals of *Alcea ficifolia*.

DR. HANS GADOW has been appointed to the Strickland Curatorship in the University of Cambridge, vacated by the resignation of Mr. Salvin, F.R.S. Dr. Gadow began his biological studies under the late Prof. Peters in the University of Berlin, but graduated at Jena, whence he proceeded to Heidelberg, and worked there under Prof. Gegenbaur. Coming to England about two years ago, he was engaged, at the suggestion of Dr. Günther, by the Trustees of the British Museum to determine the specimens to be included in volumes viii. and ix. of their collection. The product of his labours in this direction is still in the press, but his contributions to the *Journal für Ornithologie*, the *Proceedings of the Zoological Society*, and other scientific journals, show him to be one of the most promising of the rising generation of ornithologists. In October last Dr. Gadow was appointed to deliver a course of lectures on the Morphology of the Vertebrata in the University of Cambridge, which has given much satisfaction to all concerned.

WE regret to announce the death of Dr. Wilhelm Peters, Professor of Zoology at Berlin University, and Director of the Zoological Museum of that city. He died on April 20, aged sixty-seven. The death is also announced of Dr. Gustav Radicke, Professor of Mathematics at Bonn University. He died at Bonn on April 18, in his seventy-third year.

The President of the Parkes Museum, H.R.H. the Duke of Albany, has fixed Saturday, May 26, for the opening of the Museum in its new premises, 74A, Margaret Street, W. The central position of the new premises will make the Museum more useful than it has hitherto been to professional men, owners of property, employers of labour, artisans and others, both men and women; and in order that the benefits of the Museum may be extended to all classes, it will be open daily between the hours of ten and seven, during which hours admission will be free, from five to seven and from two to nine on Mondays and Saturdays; while free admission to the library and reading-room may always be had on the recommendation of a member.

The honour of a baronetcy has been conferred upon Mr. Spencer Wells.

Messrs. Macmillan and Co. are about to publish "Elementary Lessons in Practical Physics," by Prof. Balfour Stewart and Mr. Gee, Demonstrator in the Physical Laboratory at Owens College, Manchester.

The *Indian Pioneer* states that a member of the Alpine Club, attended by an experienced Swiss guide, has left Darjeeling, for the purpose of attempting the highest possible ascent of the Kinchinjunger. The task will be a hard one, especially as the difficulties to be overcome are in many respects altogether different from those encountered in Switzerland.

A tornado of wide range and great force swept over the states of Mississippi, Georgia, and South Carolina on Sunday week, killing large numbers of people and injuring many more, and destroying hundreds of buildings. The first place struck is stated to have been Georgetown, Mississippi. The tornado is said to have cut a path 1000 yards wide through a swamp in Barnwell county, South Carolina, felling the timber as neatly as if it had been cut to form a highway.

The diary of the Marquis Tseng, Chinese Minister in London, to which attention has been already drawn in the *Pall Mall Gazette*, contains one or two passages which will be of especial interest to readers of Nature. His Excellency is in favour of the acquisition of a knowledge of foreign languages by Chinese youth; he thinks that, "if young people with good vocal organs were made to apply themselves, during the intervals of school duties, to the study of a foreign language, they could gain a fluent knowledge of it in four or five years." The sudden withdrawal of the Chinese educational mission in the United States a year ago was the subject of much astonishment abroad, but the Envoy's views on the subject before the mission was despatched in the first instance, will explain the mystery. "The result of sending boys who had not studied their own classics to devote themselves exclusively to the acquisition of Western knowledge in a country like America, where there was no distinction of classes, would be simply to contribute so many citizens to the United States, and to furnish the foreign firms at the Treaty Ports with compradores and interpreters." The advantages derived by the youths in America were far less than the successes of the pupils at the Foreign College in Peking and the schools at Shanghai and Foochow. A Mr. Chang, whom the envoy met in Shanghai, and whose opinion he seems to have valued highly, suggested the establishment at Government expense of a Chinese school for foreigners, where a knowledge of the Chinese language and literature might be attained. The students, he hoped, would translate foreign books for diffusion in China. In addition translations of the educational curriculum used in schools and colleges in the West should be made, and schools where young Chinese might be trained "upon the system practised in olden times, with a slight admixture of foreign methods," should be established. "Education," Mr. Chang says, "is the basis of State administration, and its success is essential to the establishment of proper government." Marquis Tseng does not precisely claim that China in times past had steamers and steam engines, although his language at first sight seems capable of such interpretation; he says, however, that China had no lack of mechanical appliances until her material prosperity declined, when her people fell into idle and thriftless habits, and the mechanical art was lost in transmission. He prophecies that the day will arrive here as it has in China, "when Western workcraft, now so deft, will grow inept, and Western ingenuity give way to homelike simplicity. The fact is," he concludes, "the earth's productions being limited, are not sufficient to provide for the manifold wants of its countless people, and deterioration is one of nature's laws." His Excellency is clearly a man of remarkable shrewdness and capacity; let us hope that to his other gifts he does not add that of prophecy.

The *North China Herald* reports that Dr. Bretschneider, the physician to the Russian Mission in Peking, and one of the ablest and most industrious students of China, is about to leave that country for ever. Dr. Bretschneider is, we believe, chiefly a botanist, and a few months ago we noticed an elaborate paper of his on Chinese botanical knowledge; but he has laboured in many other fields of research. One of his best known works is a pamphlet on the Early Chinese Travellers in Central Asia, which was published a few years ago. The same journal states that this gentleman, although he has already published much, is reserving his *magnum opus* until his return to Europe. The great advantage of sinologues working in China and Chinese literature on the subjects of which they are otherwise masters is obvious. Thus a botanist, with a knowledge of Chinese, will clearly work to greater advantage on Chinese knowledge of botany, the flora of China, and similar subjects, than he will in any other subject, or than a non-botanical Chinese scholar can do. Dr. Bretschneider seems during his long residence in China to have recognised this, and certainly in his hands the already great scientific reputation of the Russians in Peking has not suffered.

The work of education in Hong Kong would appear to be conducted under some curious difficulties. Dr. Eitel, the Inspector of Schools, in his last report mentions that he noticed several cases in which Chinese girls, living at a great distance from school, and having to traverse on their way to and fro the most crowded portion of the town, were dressed like boys, and attended the girls' schools all through the year in boys' dresses. This was owing to the prevalence of the practice of kidnapping girls, and the curious change of dress was adopted to deceive the kidnappers.

We notice in M. Bunge's review of "European Literature in Chemical Technology," published in the *Journal of the Russian Chemical Society*, the appearance of an elaborate Russian work, by M. Radivanovsky, on "Gunpowder, Pyroxyline, Dynamite, and other Explosives," in two large volumes, one of which is devoted to theory, and the other to practice. M. Bunge considers it as decidedly the best work on the subject in Europe for its completeness and lucidity of exposition.

M. Yagu, of the Russian Physical Society, while making experiments with a new parachute-hydromotor on the Neva, came to the unexpected result that the velocity of the current in this river is only half the rate in winter that it is during the summer. It is supposed that this retardation depends upon accumulations of ice at the outflow of the Neva from Lake Ladoga, which accumulations diminish the section of the channel.

M. Pompeieu has made, before an immense crowd, two successful ascents with an elongated balloon (measurement 1300 cubic metres, elongation 1 to 3½). On both occasions the

descent was very well executed, although the balloon was partly empty, having ascended to an altitude of 1200 metres. Four persons were on board. In the second ascent M. Pompeieu obtained a movement of his aërial craft in the required direction by only moving his rudder. This circumstance is accounted for by the balloon progressing with a less velocity than the wind, owing to its elongation.

THE French Military Engineers have suggested a scheme for extending the area of Paris by suppressing the old fortifications, which cover 2000 acres, and could be sold for building-ground. The proposal is simply to connect the several forts built by Louis Philippe by a trench sufficient to prevent a sudden attack. This new line of defence would utilise the Seine and Marne as a defensive work. The total area of Paris would then be 100 square miles instead of 30, as at present.

THE Anniversary Meeting of the Zoological Society was held on April 30, Prof. W. H. Flower, LL.D., F.R.S., President, in the chair. The Report of the Council on the proceedings of the Society during the year 1882 was read by Mr. P. L. Sclater, F.R.S., the Secretary of the Society. The Report stated that the number of Fellows on December 31, 1882, was 3213, the same as at the corresponding period in 1881. The total receipts for 1882 had amounted to 34,270*l.*, against 25,810*l.* for 1881. The ordinary expenditure for 1882 had been 26,109*l.*, against 24,651*l.* for 1881, and the extraordinary expenditure 3266*l.*, against 1036*l.* for the preceding year; besides which the sum of 1000*l.* had been devoted to the repayment of part of the mortgage debt due on the Society's freehold premises, which had been thus reduced to 5000*l.* The balance carried forward for the benefit of the present year was 3891*l.* The most important work undertaken in the Gardens during the past year had been the new Reptile House, a site for which, in the south-eastern corner of the Gardens, had been selected some time since. The building was stated to be 120 feet long, by 60 feet in width. Fixed cages for the pythons and larger reptiles would occupy three sides, while the south front was reserved for small movable cases. A large oval tank for crocodiles and two smaller ones for water tortoises would be placed in the centre of the building, which it was hoped would be ready for opening in July or August next. The visitors to the Society's Gardens in 1882 had been 849,776, against 648,694 in 1881, the number having been unusually augmented by the excitement caused at the removal of the large African elephant, "Jumbo," in the beginning of the year. The number of animals in the Society's Collection on December 31 last was 2355, of which 750 were mammals, 1364 birds, and 241 reptiles. The usual ballot having been taken, it was announced that Prof. Bush, F.R.S., Major-General Henry Clerk, R.A., F.R.S., the Hon. J. S. Gathorne-Hardy, Mr. Arthur Grote, and Lord Walsingham, had been elected into the Council in place of the retiring Members, and that Prof. W. H. Flower, LL.D., F.R.S., had been reelected President, Mr. Charles Drummond, Treasurer, and Mr. Philip Lutley Sclater, M.A., Ph.D., F.R.S., Secretary to the Society for the ensuing year. The meeting terminated with the usual vote of thanks to the Chairman, in returning thanks for which Prof. Flower called attention to the loss the Society had suffered by the death of two distinguished Foreign Members (Prof. Troschel and Dr. W. Peters), and more recently by the death of the accomplished Prosector, Mr. W. A. Forbes, at the early age of twenty-eight years.

THE Sunday Society opened the Suffolk Street Galleries on Sunday for four hours to persons who had previously written for tickets. The number of visitors was 1695 (from two to four there were 495, and from six to eight the attendance was 1200). During the evening a meeting was held in the large gallery, Mr. Mark H. Judge in the chair. On the motion of Mr. Hastings Sands, seconded by Mr. Robson J. Scott, a petition in support of Lord Dunraven's resolution was unanimously passed. The annual meeting of the Society will be held on Saturday at the Princes' Hall, Piccadilly.

THE Charing Cross and Waterloo Electric Railway Bill has been withdrawn for the present session.

ON April 8, at 9 p.m., an earthquake was observed in Finland, where this phenomenon is extremely rare. At Nykarleby the shocks were rather severe, and were accompanied by a subterranean rattling and rumbling noise; their direction was from S.W. to N.E. At Wasa the ground oscillated to an alarming extent. At Ytterjeppo even the houses were shaken to their foundations and their downfall was feared; the same intensity in the shocks was observed on the "domaine" of Back.

MR. R. MELDOLA writes to say that an error has inadvertently crept into his address, referred to in last week's NATURE (p. 615). The remark quoted was not made with reference to Mr. Wallace's paper, published by the Linnean Society in August, 1858, but with reference to his first paper, "On the Law which has Regulated the Introduction of New Species," published in the *Annals and Magazine of Natural History* for September, 1855. This mistake, however, does not affect the general tenor of our paragraph.

A PAPER issued by the Isthmus of Corinth Canal Company states that the explosions of the mines will be made with an electric machine moved by hand and Leyden jar. The total weight of dynamite required will amount to 2,500,000 pounds. The work is expected to last four years, and to cost about 1,100,000*l.* The canal will be 6300 metres in length, 22 in breadth, and 8 in depth.

THE Rev. James Sibree has issued in a separate form his instructive paper on Malagasy Place-Names, which originally appeared in the *Journal* of the Royal Asiatic Society.

DR. RUDOLF FALB, the well-known author of various works on earthquakes and volcanoes, has recently written an interesting little book entitled "Wetterbriefe." It contains reflections on meteorology, with special reference to the inundations of 1882, which the author considers to be periodical. The book is published by Hartleben of Vienna.

DR. JOS. CHAVANNE'S edition of Adrian Balbi's "Allgemeine Erdbeschreibung," to which we have already referred some time ago, and which is in course of publication by Hartleben (Vienna), has now reached the twenty-fourth part. It will be completed in forty-five parts.

THE illustration of the "Lion at Rest," lent to us by our Paris contemporary, *La Nature*, which appeared in our issue of April 19, was, we are now informed, engraved from a photograph by Mr. Thomas James Dixon, the copyright of which belongs to Mr. Henry Dixon, of 112, Albany Street, Regent's Park.

THE additions to the Zoological Society's Gardens during the past week include a Macaque Monkey (*Macacus cynomolgus*) from India, presented by Mr. H. G. Wainwright; a Leopard (*Felis pardus* ♂) from East Africa, presented by Capt. Percy Luxmore, R.N., C.B.; a Brown Bear (*Ursus arctos* ♂) from Kamschatka, presented by Mr. C. T. Kettlewell; a Ring-tailed Coati (*Nasua rufa*) from South America, presented by Mr. Dudley Sheridan; a Common Badger (*Meles taxus*), British, presented by Mr. J. Snowden Henry, F.Z.S.; a Woodcock (*Scolopax rusticola*), British, presented by Capt. Nicholls; two Edible Snails (*Helix pomatia*) from Cheltenham, presented by Lieut.-Col. C. S. Sturt, C.M.Z.S.; an Ashy-black Macaque (*Macacus ocreatus*) from the East Indies, a Senegal Parrot (*Pœocephalus senegalensis*) from West Africa, deposited; a Great Anteater (*Myrmecophaga jubata*) from Brazil, a Common Sparrow Hawk (*Accipiter nisus*), British, purchased.

CHEMICAL NOTES

THAT the statement of the "law of isomorphism" given by Mitscherlich is not applicable to all cases of isomorphous salts has been recognised for some time. M. Klein has recently described certain pairs of salts which crystallise in identical forms, but are not of similar chemical composition; thus *tungsto-boric acid*, $9WO_3 . B_2O_3 . 2H_2O$, is isomorphous with *silico-tungstic acid*, $12WO_3 . SiO_2 . 4H_2O$. M. Klein proposes to state the *law of isomorphism* in the following terms:—"Isomorphous bodies have either similar chemical composition, or exhibit only small differences in percentage composition; they contain either a common group of elements, or groups of elements of identical chemical formation which form by far the greater part of their weight" (*Compt. Rend.* xcv. 781).

THE rare metal thorium has been obtained in some quantity and in a pure state by Nilson. The properties of this metal are described in *Compt. Rend.* xcv. 727 *et seq.*: the sp. gr. is 11, and the atomic weight 232·36.

F. M. RAOULT (*Compt. Rend.* xcv. 1030) has studied the reduction of freezing-point of a liquid caused by the solution in it of a solid substance. He concludes that a molecule of any compound dissolved in 100 molecules of any liquid of a different nature lowers the freezing-point of the liquid by a nearly constant amount (about 0°·62). This law, he asserts, is general if it is admitted that physical molecules may be composed of two, and in some few cases of three chemical molecules.

WROBLEWSKI (whose experiments have been already referred to in these notes) states (*Ann. Phys. Chem.* [2], xix. 103) that if a little water is introduced into a tube containing CO_2, the whole cooled to 0°, the pressure increased till the CO_2 liquefies, and then suddenly released, care being taken that the pressure does not fall below 12·3 atmospheres, a thin opaque solid forms on the surface of the water, which solid is a definite hydrate of carbon dioxide. Further experiments are detailed, showing that the probable formula of this hydrate is $CO_2 8H_2O$.

M. SPRING continues his investigation on the influence of great pressure on chemical action (*Berichte*, xvi. 324). He has succeeded in preparing definite arsenides of zinc, lead, tin, cadmium, copper, and silver.

A NEW method for preparing the paraffins (C_nH_{2n+2}) has been found by Herr Köhnlein, a student in Prof. Lothar Meyer's laboratory at Tübingen; the method consists in heating together pure dry aluminium chloride and the normal iodide of the paraffin radicle required; *e.g.* $AlCl_3$ and C_3H_7I yield pure C_3H_8; $AlCl_3$ and C_2H_5I yield pure C_2H_6, &c.

AFTER having published his important work on the etherisation of alcohols, Prof. Menshutkin now publishes in the *Journal of the Russian Chemical Society* a new paper on the methods of qualitative determination of aniline and analogous bases which have no alkaline reaction, as well as of triethylamine and similar bases, and of ammonia. All these methods are a generalisation of the method of alkalimetry, and the discovery of them has afforded the author the possibility of studying the classic reaction of the permutation of bases in solutions of their neutral salts. This last is the subject of his first paper. The reaction being made under the most simple unvarying physical conditions, M. Menshutkin begins with the study of complete permutations, and shows that the theory of Berthollet as to the influence of the chemical mass is not true with regard to aniline, which is completely substituted in salts by bases whose temperature of combination with hydrochloric acid is greater than for aniline; the same is true with regard to triethylamine, which is also substituted completely, notwithstanding the increase of its chemical mass, and to ammonia. These researches have led the author to a new method of titration by means of the alcoholate of barium, and to a means of studying the formation and dissociation of acetylanilide, as well as of the amides.

ON THE SUPPOSED PRE-CAMBRIAN ROCKS OF ST. DAVID'S[1]

THE author began by briefly narrating the circumstances under which he had been led to study the geology of St. David's. He had visited the district twice—first in company with Mr. B. N. Peach, with whose cooperation nearly all the field work was done, and again in conjunction with Mr. W. Topley. The paper was divided into two parts, the first being mainly controversial, and the second descriptive.

According to Dr. Hicks, there are at St. David's three distinct pre-Cambrian formations: the "Dimetian," consisting of crystalline, gneissic, and granitoid rocks; the "Arvonian," formed of felsites, quartz-porphyries, hälleflintas, and other highly-silicated rocks; and the "Pebidian," composed of tuffs, volcanic breccias, and basic lavas. He regards the "Arvonian" as later than and unconformable to the "Dimetian," and the "Pebidian" as younger than, and unconformable to both; and he asserts that the basement conglomerate of the Cambrian system lies quite unconformably on all these rocks, and is in great part made up out of their waste.

Taking up each of these groups in the order of sequence assigned to them, the author maintained that the "Dimetian group" is an eruptive granite, which has disrupted and altered the Cambrian strata, even above the horizon of the supposed basal conglomerate. He described a series of natural sections where this relation is exposed, particularly one on the coast at Ogof-Llesugn, where the conglomerate has been torn off and involved in the granite, and has been intensely indurated, so as to become a kind of pebbly quartzite. No other rock occurs within the granite mass except dykes of diabase, which rise through all the rocks of the district, but are especially abundant in the granite. The veins of finer granite, so general in granite areas are conspicuous here. In short, whether studied in hand specimens or on the ground, the rock is so unmistakably an eruptive mass that the author could not understand how this view, which was that expressed on the Geological Survey maps, should ever have been called in question. The manner in which it has risen across the bedding of successive horizons in the Cambrian series proves that, instead of being a pre-Cambrian gneiss, it must be much younger than all the Cambrian rocks of the district.

The "Arvonian group" consists of quartziferous porphyries, or elvans, associated with the granite, and of the metamorphosed strata in their vicinity. Reference was made to natural sections where the actual intrusion of the elvans across the bedding of the rocks could be seen.

The "Pebidian group" comprises a series of volcanic tuffs and breccias, with interstratified and intrusive lavas. The author maintained that this group forms an integral part of the Cambrian system as developed at St. David's. It has been broken through by the granite and porphyries, and is therefore of older date. Instead of being covered unconformably by the Cambrian conglomerate, as asserted by Dr. Hicks, the volcanic group is overlain quite conformably by that rock; and seams of tuff are interstratified with the conglomerate and occur on various horizons above it. The conglomerate, instead of being mainly composed of fragments of the rocks beneath it, consists almost entirely of quartz and quartzite, only 4 per cent. of fragments having been found to have been derived from some of the projecting lava-islands underneath it.

From the evidence now brought forward, the author contended that as the names "Dimetian," "Arvonian," and "Pebidian" had been founded on error of observation, they ought to be dropped out of geological literature.

In the second part of his paper the author gave the results of the survey which he had made of the district with Messrs. Peach and Topley, and of his study of a series of more than 100 thin slices of the rocks collected at St. David's. He found that he could corroborate generally the descriptions of previous writers on the microscopic structure of the rocks, and that investigation with the microscope amply confirmed the deductions he had drawn from observations in the field.

1. *Order of Succession of the Rocks.*—The following rock-groups in the Lower Cambrian series are recognisable at St. David's, and are given in descending order:—

4. Purple and greenish grits, sandstones, and shales.
3. Green and red shales and sandstones, with thin tuffs (*Lingulella primæva*).
2. Quartz conglomerate.
1. Volcanic group (tuffs, schists, lavas).

The volcanic group forms the oldest part of the Cambrian series at this locality. The bottom is not reached, but about 1800 feet are visible. It consists mainly of purplish-red, green, grey, and pale tuffs, with occasional breccias and bands of olivine-diabase. Analyses of some of these rocks had been

[1] Abstract of a paper read at the Geological Society by Archibald Geikie, F.R.S.

made for the author by M. Renard of Brussels, and Mr. J. S. Grant Wilson of the Geological Survey of Scotland. The tuffs are partly basic, derived from the disruption of diabase lavas (48 per cent. of silica), partly acid, from the destruction of felsites (72 to 80 per cent. of silica). The microscopic structure of the tuffs was described, and slides and drawings were exhibited. The lavas are varieties of olivine-diabase. Their augite is remarkably abundant and fresh, and they contain scattered larger well-formed, as well as imperfect, crystals of olivine, generally in the form of hæmatitic pseudomorphs. No instance was observed of a siliceous lava having been erupted at the surface. The felsitic fragments in the tuffs must have been derived from the explosion of lavas that do not seem to have flowed out above ground. It was pointed out that this fact is exactly paralleled in the case of the volcanic group of the Lower Old Red Sandstone in the Pentland Hills.

In relation to the quartz-conglomerate, allusion was made to the constant recurrence of such conglomerates in the series of geological formations, and to the fact that they do not necessarily mark unconformability or the natural base of groups of sedimentary rocks.

2. *Geological Structure of the District.*—It was shown that the rocks have been folded into an isocline or inverted anticline, so that in one-half of the plication the dip of the strata is reversed.

The groups above mentioned are found in their proper order on both sides of the axis which runs through the volcanic group. The granite has risen irregularly through the eastern limb of the isocline. Small faults may occur here and there along the edge of the granite, but they do not in any way affect the general structure.

3. *The Foliation of the District.*—There has been extensively developed at St. David's a fine foliation of particular kinds of rock, more especially of certain fine tuffs and shales, which have passed into the condition of fine silky unctuous hydro-mica-schists or sericite-schists. A series of microscopic slices was described, which showed that the original clastic structure of the beds remains quite distinct, though an abundant development of fine flakes of a hydrous mica has taken place. This structure more particularly characterises the fine parts of the volcanic group, but it occurs also on various horizons in the groups above the conglomerate, thus linking the whole as one great continuous series of deposits. The author connected it with the plication of the district, and pointed out the great interest attaching to these fine schistose bands as revealing some of the incipient stages of the same process that had changed wide regions of sedimentary strata into crystalline schists.

4. *The Granite, Quartz-Porphyries, and accompanying Metamorphism.*—The petrographical characters of these eruptive rocks were described, and their perfect analogy to the familiar granites and elvans of other districts was pointed out. Specimens were shown illustrating the gradation from a true granite into spherulitic quartz-porphyry. The quartz-porphyries of St. David's (described by Mr. Davies, Dr. Hicks and others) exhibit spherulitic structure in an exceptionally perfect manner. Between the felso-spherulites the base is thoroughly micro-crystalline and not felsitic. The rocks belong to a group intermediate between granites and felsites. They occur in bosses, elvans, or dykes round the granite, cutting through all horizons of the volcanic group, and approaching, if they do not actually intersect, the quartz-conglomerate. The metamorphism associated with the granites and porphyries is best seen near the latter. It consists chiefly in the intense induration of certain bands of rock which have been converted into flinty aggregates (adinole). The alteration takes place usually along the bedding, which is nearly vertical; but veins of the same siliceous material ramify across the stratification of the shales. Examined microscopically, the adinole is found to have acquired a micro-crystalline structure, nests of quartz and orthoclase and porphyritic crystals of plagioclase having been developed, together with fine veins and filaments of crystalline quartz. These veins are here and there crowded with approximately parallel partitions of liquid inclusions showing freely moving bubbles. An analysis of a portion of the adinole, made for the author by M. Renard, shows the percentage of silica to be 78·62 with 5·80 of soda, indicating possibly the formation of albite. The author deferred generalising on the question of the metamorphism he described, but pointed out that a further study of the St. David's rocks could hardly fail to throw important light on the theory of metamorphism.

5. *The Diabase Dykes and Sheets.*—These are the latest rocks at St. David's, as they traverse all the others. Their macroscopic and microscopic characters were described, and allusion was made to the perfect fluxion-structure found in many of the dykes.

The paper closed with a summary of the geological history of St. David's. The earliest records are those of the volcanic group, which show the existence of volcanic vents in that region in an early part of the Lower Cambrian period. The volcanic accumulations were covered conformably by the conglomerate and succeeding Cambrian groups; but the same kind of tuffs continued to be ejected after the deposition of the conglomerate. At a later time this thick conformable succession of beds was plicated, and underwent a partial metamorphism, whereby some of the fine tuffs and shales were converted into sericite-schists. Subsequently a mass of granite rose through one side of the fold, accompanied by elvans of spherulitic quartz-porphyry, whereby a second, different, and feebler kind of metamorphism was induced. The last episode was that of the diabase dykes, which, crowded together in the granite, suggest that the granite boss stands on an old line of weakness and of escape for eruptive material from the interior.

As the conclusions drawn by the author from his study of the microscopic structure of the rocks of St. David's had been called in question at the reading of the first part of the paper, he took an opportunity before the reading of the second part to submit a series of typical specimens and microscopic slides to Professors Zirkel of Leipzig, Renard of Brussels, and Wichmann of Utrecht. These observers amply sustained his deductions. M. Renard came from Brussels to be present at the reading of the second part, and in the course of the discussion stated that Professors Zirkel, Wichmann, and himself had arrived at the following conclusions regarding the rocks of St. David's:—

1. The so-called "Dimetian" rock of St. David's is unquestionably a true granite. 2. The quartz-porphyries are just such rocks as might be expected to occur as apophyses of the granite, and the specimens from Bryn-y-Garn, Rock House, and St. David's left no doubt on their minds that such is really their origin. They cannot be confounded with rhyolitic lavas. 3. The conglomerate from the granite-contact shows secondary quartz between its pebbles. 4. The bands of fine tuff found intercalated with, and on various horizons above, the conglomerate, consist of true tuff, and cannot have been derived from the mere superficial waste of older volcanic rocks. 5. Fine foliation is well developed among the strata above the conglomerate as well as in the volcanic group below.

SOLAR PHYSICS[1]

THE lecturer introduced his subject by drawing attention to the circumstance that the idea of the sun being an exceedingly hot body was of very modern date, that both ancient and modern writers up to the early portion of the present century attributed to him a glorious and supernatural faculty of endowing us with light and heat of the degree necessary for our wellbeing, whilst even Sir William Herschel had attempted to find an explanation to account for his idea that the body of the sun might be at a low temperature, and inhabitable by beings similar to ourselves, which he did in surrounding the inhabitable surface by a non-conducting atmosphere—the penumbra—to separate it from the scorching influence of the exterior photosphere.

It was not till the views of Kant, the philosopher, had been developed by Laplace, the astronomer, in his famous "Mécanique Céleste," that the view gained ground that our central orb was a mass of matter in a state of incandescence, representing such an enormous aggregate as to continue radiation into space for an almost indefinite period of time.

The lecturer illustrated by means of a diagram the fact that of all the heat radiated away from the sun only 1/2,250,000,000 part could fall upon the surface of our earth, vegetation and force of every kind being attributable to this radiation, whilst all but this fractional proportion apparently went to waste.

Recent developments of scientific research had enabled us to know much more of the constitution of the sun and other heavenly bodies than had formerly been possible. Comte says in his "Positive Philosophy" (Martineau's translation of 1853) that "amongst the things impossible for us ever to know was that of telling what were the materials of which the sun was

[1] Abstract of Lecture at the Royal Institution, by Sir William Siemens, F.R.S., April 27.

composed" ; but within only seven years of that time Messrs. Bunsen and Kirchhoff published their famous research showing that, by connecting the dark Fraunhofer lines of the solar spectrum with the bright lines observed in the spectra of various metals, it was possible to prove the existence of those substances in the solar photosphere, thus laying the foundation of spectrum analysis, the greatest achievement of modern science. Dr. Huggins and others, applying this mode of research to other heavenly bodies, including the distant nebulæ, had extended our chemical knowledge of them in a measure truly marvellous.

Solar observation had thus led to an analytical method by which chemistry had been revolutionised, and it would be, in the lecturer's opinion, through solar observation that we should attain to a much more perfect conception of the nature and effect of radiant energy, in its three forms of heat, light, and actinism, than we could as yet boast of. The imperfection of our knowledge in this respect was proved by the circumstance that whereas some astronomers and physicists, including Waterston, Secchi, and Ericsson, had, in following Sir Isaac Newton's hypothesis, attributed to the sun a temperature of several millions of degrees Centigrade, others, including Pouillet and Vicaire, in following Dulong and Petit, had fixed it below 1800° C. ; between these two extremes other determinations based upon different assumptions had placed the solar temperature at between 60,000° and 20,000°.

The lecturer, having conceived a process by which solar energy may be thought self-sustaining, had felt much interested for some years in the question of solar temperature. If the temperature of the solar photosphere should exceed 3000° C., combustion of hydrogen would be prevented by the law of dissociation, as enunciated by Bunsen and Sainte-Claire Deville, and his speculative views regarding thermal maintenance must fall to the ground. To test the question he in the first place mounted a parabolic reflector on a heliostat, with a view of concentrating solar rays within its focus, which, barring comparatively small losses by absorption in the atmosphere and in the metallic substance of the reflector should reproduce approximately the solar temperature. By introducing a rod of carbon through a hole at the apex of the reflector until it reached the focus, its tip became vividly luminous, producing a light comparable to electric light. When a gas burner was arranged in such a way that the gas flame played across the focal area, combustion appeared to be retarded but was not arrested, showing that the utmost temperature attained in the focus did not exceed materially that producible in a Deville oxyhydrogen furnace or in the lecturer's regenerative gas furnace, in which the limit of dissociation is also reached.

Having thus far satisfied himself, his next step was to ascertain whether terrestrial sources of radiant energy were capable of imitating solar action in effecting the decomposition of carbonic acid and aqueous vapour in the leaf-cells of plants, which led him to undertake a series of researches on electro-horticulture extending over three years, a subject which he had brought before the Royal Society and the Royal Institution two years ago. By these researches he had proved that the electric arc possessed not only all the rays necessary to plant-life, but that a portion of its rays (the ultra-violet) exceeded in intensity the effective limit, and had to be absorbed by filtration through clear glass, which, as Prof. Stokes had shown, produced this effect without interference with the yellow and other luminous and intense heat-rays. He next endeavoured to estimate the solar temperature by instituting a comparison between the spectra due to different known luminous intensities. Starting with the researches of Prof. Tyndall on radiant energy, supplementing them by experiments of his own on electric arcs of great power, and calling to his aid Prof. Langley of the Alleghany Observatory to produce for him a complete spectrum of an Argand burner, he concluded that with the temperature of a radiant source the proportion of luminous rays increased in a certain ratio : whereas in an Argand oil-burner only 2½ per cent. of the rays emitted were luminous, and mostly red and yellow, a bright gas flame emitted 5 per cent., the carbon thread of an incandescent electric light between 5 and 6 per cent , a small electric arc 10 per cent., and in a powerful 5000-candle electric arc as much as 25 per cent. of the total radiation was of the luminous kind. Prof. Langley, in taking his photometer and bolometer up the Whitley Mountain, 18,000 feet high, had proved that of the solar energy not more than 25 per cent. was of the luminous kind, and that the loss of solar energy sustained between our atmosphere and the sun was chiefly of the ultra-violet kind, which rays, if they penetrated our atmosphere, would render vegetation impossible. It was thus shown that the temperature of the solar photosphere could not materially exceed that of a powerful electric arc or indeed of the furnaces previously alluded to, leading him to the conclusion already foreshadowed by Sainte-Claire Deville and accepted by Sir William Thomson, that the solar temperature could not exceed 3000° C. The energy emitted from a source much exceeding this limit would no longer be luminous, but consist mainly of ultra-violet rays, rendering the sun invisible, but scorching and destructive of all life.

Not satisfied with these inferential proofs, the lecturer had endeavoured to establish a definite ratio between temperature and radiation, which formed the subject of a very recent communication to the Royal Society. It consisted simply in heating a platinum or iridio-platinum wire, a metre long and suspended between binding screws, by means of an electric current, the energy of which was measured by two instruments, an electro-dynamometer giving the current in amperes, and a galvanometer of high resistance giving the electromotive force between the same points in volts. The product of the two readings gave the volt-amperes or watts of energy communicated to the wire, and dispersed from it by radiation and convection. A reference to the lecturer's paper on the Electrical Resistance Thermometer, which formed the Bakerian Lecture of the Royal Society in 1871, would show that the varying electromotive force in volts observed on the galvanometer was a true index of the temperature of the wire, while being heated by the passage of the current ; a law of increase of radiation with temperature was thus established experimentally up to the melting-point of iridio-platinum, which when laid down in the form of a diagram gave very consistent results expressible by the simple formula—

$$\text{Radiation} = Mt^2 + \phi t,$$

M being a coefficient due to substance radiating.

Sir William Thomson had lately shown that the total radiating energy from a unit of surface of the carbon of the incandescent lamp amounted to 1/67 part of the energy emitted from the same area of the solar photosphere, and taking the temperature of the incandescent carbon at 1800° C. (the melting-point of platinum which can just be heated to the same point), it follows in applying Sir William Thomson's deductions to the lecturer's formula that the solar photosphere does not exceed 2700° C., or, adding for absorption of energy between us and the sun, about 2800° C.—a temperature already arrived at by different methods. The character of the curve was that of a parabola slightly tipped forward, and if the ratio given by that curve held good absolutely beyond the melting-point of platinum iridium, it would lead to the conclusion that at a point exceeding 3000° C. radiation would become as it were explosive in its character, rendering a rise of temperature beyond that limit difficult to conceive.

Clausius had proved that the temperature obtainable in a focus could never exceed that of the radiating surface, and Sainte-Claire Deville that the point of dissociation of compound vapours rises with the density of the vapour atmosphere. Supposing interstellar space to be filled with a highly attenuated compound vapour, it would clearly be possible to effect its dissociation at any point, where, by the concentration of solar rays, a focal temperature could be established, but it was argued that the higher temperature observable in a focal sphere was the result only of a greater abundance of those solar vibrations called rays within a limited area, the intensity of each vibration being the outcome of the source whence it emanated : thus, in the focal field of a large reflector, the end of a poker could be heated to the welding point, whereas in that of a small reflector the end of a very thin piece of wire only could be raised to the same temperature. If, however, a single molecule of vapour not associated or pressed upon by other molecules could be sent through the one focus or the other, dissociation in obedience to Deville's law must take place irrespective of the focal area ; but inasmuch as the single solar ray represented the same potential of energy as numerous rays associated in a focus, it seemed reasonable that it should be as capable of dealing with the isolated molecule as a mere accumulation of the same within a limited space, and must therefore possess the same dissociating influence. Proceeding on these premises, the lecturer had procured tubes filled with highly attenuated vapours, and had observed that an exposure of the tubes to the direct solar rays or to the arc of a powerful electric light affected its partial or entire dissociation ; the quantity of matter contained within such

a tube was too slight to be amenable to direct chemical test, but the change operated by the light could be clearly demonstrated by passing an electric discharge through two similar tubes, one of which had and the other had not been exposed to the radiant energy from a source of high potential. If space could be thought to be filled with such vapour, of which there was much evidence in proof, solar rotation would necessarily have the effect of drawing such vapour towards its polar surfaces and emitting it equatorially by an action independent of solar gravity, and which might be likened to that of a blowing fan. When reaching the solar photosphere, this circulating dissociated vapour would, owing to its accumulated density, flash into flame, and could thus be made to account in great measure for the maintenance of solar radiation, whilst its continual dissociation in space would account for the continuance of solar radiation into space without producing any perceivable calorific effect.

Time did not permit him to enter more fully on these subjects, which formed part of a solar hypothesis which he had ventured lately to bring forward, his main object on this occasion having been to elucidate the point of cardinal importance to that hypothesis, that of the solar temperature.

The lecture was illustrated by several experiments, showing the methods by which the dependence of radiation upon temperature had been arrived at.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE

CAMBRIDGE.—Mr. H. Marshall Ward, M.A., late Scholar of Christ's College, First Class in the Natural Sciences Tripos, 1879, Lecturer at Owens College, and Fellow of Victoria University, has been elected Fellow of Christ's College.

It is proposed to appoint a Curator of the new Archæological Museum at Cambridge at a stipend of 150*l* a year. Valuable contributions towards developing the Museum in the direction of ethnology have been promised.

In a discussion on the proposed immediate appointment of a Professor of Physiology, it was mentioned that enlarged class-rooms and a lecture-room, which did not exist, would be needed. A hope was expressed that the Professorship of Pathology would be filled up as soon as there was a reasonable prospect of sufficient appliances in the form of laboratory, &c., being provided for the Professor.

MR. W. N. STOCKER, M.A., Fellow of Brasenose, has been appointed Professor of Physics at the Royal Indian Engineering College, Cooper's Hill. Mr. Stocker took a first-class in mathematics and also in natural science, and has been for the last eight years Demonstrator in the Clarendon Laboratory.

SCIENTIFIC SERIALS

Journal of the Russian Chemical and Physical Society, vol. xv. fasc. 1.—Researches on the naphtha of Caucasus, by MM. Beilstein and Kurbatoff. The naphtha from Bakou consists mostly of hydrocarbons of the C_nH_{2n} series, identical with the products of hydrogenisation of the aromatic series C_nH_{2n-6}. That of the Tzarskiye Kolodtsy has a different composition; it contains but little of the hydrocarbons of the C_nH_{2n} series, but chiefly those of the C_nH_{2n+2} types, with a mixture of those of the aromatic series C_nH_{2n-6}. This analysis explains why the petroleum derived from the Bakou naphtha, although having a greater density together with the same volatility, burns brighter than the American, as also the higher qualities of the oils received from this naphtha. Its hydrocarbons being all liquid it contains but little paraffin, and the greasing oils may be cooled to lower temperatures, without liberating paraffin.—On the use of hyposulphite of ammonium, instead of the sulphide of ammonium, in qualitative analysis, by A. Orlovsky.—On the hydrogenisation of turpentine and cymol, by P. Orloff.—Additions to the theory of the action of chloride of ammonium.—On the evaporation of liquids, by B. Sreznewsky, being the conclusion of a treatise which has appeared in several preceding numbers of the *Journal*. The conclusions arrived at are: the velocity of evaporation is not constant; the velocity of evaporation of drops depends upon their height, and increases as the height diminishes; at a height of an average size it is proportioned to the periphery of the basis.—An aërial calorimeter (a project of), by N. Hesehus.—Elementary demonstration of the pendulum formulæ, by V. Wolkoff.

Vol. xv. fasc. 2.—On the transformation of the primary radical of propyl into a secondary, being a continuation of the researches undertaken by MM. Kékulé and Schröter, on the transformation of bromide into isopropyl under the influence of alluminium bromide.—On the heat of dissolution of mixtures of salts, and on the principle of maximum work, by P. Chrustchoff.—Analysis of the mineral waters of Slavinsk, in the Government of Lublin, by M. Kondakoff. They may be considered as one of the best iron mineral waters, as they contain the least mixture of other mineral substance; that is, 0·19 to 0·22 parts of carbonate of iron out of 3·18 to 3·38 parts of other salts, against 0·37 to 4·36, contained in the water of Spa, or 0·45 to 6·14, and 0·24 to 5·45 in those of Altwasser and Reinerz.—On the chloride of pyrosulphuryle, by D. Konovaloff.—Analysis of sulphur concretions in the fireproof clay from Bakhmut, by M. Kondakoff.—On the structure of nitric compounds of the fatty series, by M. Kissel.—On the permutations of bases in solutions of their neutral salts, by Prof. Menshutkin (analysed elsewhere).—On the specific heat of several products of distillation of naphtha, by E. Kuhlin.—On a secondary product obtained during the preparation of allyldimethyl carbinol, by W. Dieff; it distilled at 165° to 185°, and its structure may be represented as $C_9H_{18}O$.—On the critical temperature of isomeric and homologous series, by A. Nadejdine. The supposition formerly made by the author as to the critical temperature increasing in the same proportion as the temperature of boiling is confirmed by experiments with a sufficient degree of accuracy; it would result that the functions which express the dependency of the critical temperature upon the molecular structure are the same as those expressing the same dependency of the temperature of boiling, and differ only by their constants.—On comets and solar radiation, by M. Schwedoff.—Several conclusions from the theorem of Carnot, by M. Sreznewsky, being a confirmation of the formula of Kirchhoff ("Ueber einen Satz der mechanischen Wärmetheorie") for the expression of the absorption of heat during the formation of saturated solutions, and a verification of it for a certain number of salts.

SOCIETIES AND ACADEMIES

LONDON

Royal Society, March 8.—"Note on the Reversal of Hydrogen Lines; and on the Outburst of Hydrogen Lines when Water is dropped into the Arc." By Professors Liveing and Dewar.

The concentration of the radiation of hydrogen in a small number of spectral lines would lead us to expect that the absorption of light of the same refrangibility as those lines would, at the temperature of incandescence, be correspondingly strong, and that therefore the hydrogen lines would be easily reversed. The mass of hydrogen which can be raised to a temperature high enough to show the lines is, however, so small that, notwithstanding the great absorptive power of hydrogen for the rays which it emits, the reversal of the lines has not hitherto been noticed. In fact, the lines are very readily reversed, and the reversal may be easily observed.

When a short induction-spark is taken between electrodes of aluminium or magnesium in hydrogen at atmospheric pressure, a large Leyden jar being connected with the secondary wire of the coil, the hydrogen lines show no reversal; but if the pressure of the hydrogen be increased by half an atmosphere or even less,[1] the lines expand and a fine dark line may be seen in the middle of the F line. As the pressure is increased, this dark line becomes stronger, so that at two atmospheres it is very decided. As the F line expands with increase of pressure, the dark line expands too, and becomes a band. It is best seen when the pressure is between two and three atmospheres. When the pressure is further increased, the dark band becomes diffuse, and at five atmospheres cannot be distinctly traced. No definite reversal of the C line was observed under these circumstances. The dispersion used, however, was only that of one prism.

By using a higher dispersion the reversal of both the C and F lines may be observed at lower pressures. For this purpose a Plücker tube was used, filled with hydrogen and only exhausted until the spark would pass readily when a large jar was used.

The light of the narrow part of the tube is, under these cir-

[1] The metallic gauge connected with the Cailletet pump used is not at all sensitive, so the pressures here mentioned are only approximate.

cumstances, very brilliant, while the spark in the broad ends is wider and less bright, but does not fill the tube. On viewing such a tube end on, and projecting the image of the narrow part of the tube on to the slit of the spectroscope, a continuous spectrum of the width of the image of the narrow part of the tube is seen, besides the lines of hydrogen given by the discharge in the wide part of the tube. These lines extend above and below the narrow continuous spectrum if the electrode is well placed so that half an inch or so of the spark in the wide part of the tube may intervene between the narrow part of the tube and the spectroscope. The continuous spectrum of the narrow part of the tube seems due chiefly to the expansion of the hydrogen lines when the discharge occurs in so confined a space, and it is much brighter than the lines given by the spark in the wide part of the tube. Where the latter cross the continuous spectrum a very evident absorption occurs. The authors observed it with a diffraction grating. The C line in the third order falls so near the F line in the fourth that both may be observed together. F is much more expanded than C, and the reversal consequently less marked though quite plain. The other lines being still more diffuse, their absorption could not be traced.

The authors have before observed (*Proc. Roy. Soc.* vol. xxx. p. 157) that the C and F lines of hydrogen are visible in the arc of a De Meritens' magneto-electric machine taken in hydrogen; though in the arc of a Siemens' machine the C line can only be detected at the instant of breaking the arc, the F line hardly at all. When, instead of taking the arc in hydrogen, small drops of water are allowed to fall from a fine pipette into the arc taken in air in a lime crucible, each drop as it falls into the arc produces an explosive outburst of the hydrogen lines. Generally the outburst is only momentary, but occasionally a sort of flickering arc is maintained for a second or two and the hydrogen line C is visible all the time. The lines (C and F) are usually much expanded, but are frequently very unequally wide in different parts of the line. F is weaker, more diffuse, and more difficult to see than C, and is visible for a shorter time. There is no sign of reversal. In the explosive character of the outburst and the irregularity in the width of the lines the effect resembles that of an outburst of hydrogen in the solar atmosphere. The elements of the water are, it must be supposed, separated, but from the explosive character of the effect they are not uniformly distributed in the arc. The arc being horizontal, and the image of it projected on to the slit of the spectroscope, it was really a very small section of the arc which was under observation, and this renders the variation in the width of the lines the more remarkable.

April 5.—"On a hitherto unobserved Resemblance between Carbonic Acid and Bisulphide of Carbon." By John Tyndall, F.R.S.

Chemists are ever on the alert to notice analogies and resemblances in the atomic structure of different bodies. They long ago indicated points of resemblance between bisulphide of carbon and carbonic acid. In the case of the latter we have one atom of carbon united to two of oxygen, in the case of the former one atom of carbon united to two of sulphur. Attempts have been made to push the analogy still further by the discovery of a compound of carbon and sulphur analogous to carbonic oxide, but hitherto, I believe, without success. I have now to note a resemblance of some interest to the physicist, and of a more subtle character than any hitherto observed.

When, by means of an electric current, a metal is volatilised and subjected to spectrum analysis, the "reversal" of the bright band of the incandescent vapour is commonly observed. This is known to be due to the absorption of the rays emitted by the hot vapour in the partially cooled envelope of its own substance which surrounds it. The effect is the same in kind as the absorption by cold carbonic acid of the heat emitted by a carbonic oxide flame. For most sources of radiation carbonic acid is one of the most transparent of gases; for the radiation from the hot carbonic acid produced in the carbonic oxide flame, it is the most opaque of all.

Again, for all ordinary sources of radiant heat, bisulphide of carbon, both in the liquid and vapourous form, is one of the most diathermanous bodies known. I thought it worth while to try whether a body reputed to be analagous to carbonic acid, and, like it, so pervious to most kinds of heat, would show any change of depoitment when presented to the radiation from hot carbonic acid. Does the analogy between the two substances extend to the vibrating periods of their atoms? If it does, then the bisulphide, like the carbonic acid, will abandon its usually transparent character, and play the part of an opaque body, when presented to the radiation from the carbonic oxide flame. This proves to be the case. Of the radiation from hydrogen, a thin layer of bisulphide transmits 90 per cent., absorbing only 10. For the radiation from carbonic acid, the same layer of bisulphide transmits only 25 per cent., 75 per cent. being absorbed. For this source of rays, indeed, the bisulphide transcends, as an absorbent, many substances which, for all other sources, far transcend *it*.[1]

Chemical Society, April 19.—Dr. W. H. Perkin, president, in the chair.—The following gentlemen were elected Fellows: T. L. Briggs, J. A. Basker, J. B. Coleman, W. H. Cannon, E. C. Conrad, C. Gillett, E. C. Henning, N. K. Humphreys, L. Levy, A. Ness, V. I. Schopoff, A. E. Wilson.—The following papers were read:—On the gases evolved during the conversion of grass into hay, by P. F. Frankland and F. Jordan. The authors find that comparatively dry grass soon evolves considerable quantities of carbonic anhydride with mere traces of hydrogen and hydrocarbons; this evolution of gas occurs in air and in an atmosphere of carbonic anhydride or hydrogen; in oxygen a notable proportion of nitrogen accompanies the carbonic anhydride. Under water, grass also evolves carbonic anhydride with some hydrogen, due probably to lactic fermentation, acetic, lactic, and propionic acids being simultaneously formed.—Note on an apparatus for fractional distillation under reduced pressures, by L. T. Thorne. The object of this apparatus is to facilitate the removal of the various fractions of the distillation without breaking the continuity of the distillation.—Notes on the condition in which carbon exists in steel, by Sir F. A. Abel, C.B., and W. H. Deering. Two series of experiments are given by the authors; in the first the differences between cold rolled, annealed, and hardened samples of the same steel are investigated. The steel disks were subjected to the action of a saturated solution of potassium bichromate containing 5 per cent. by volume of sulphuric acid. In each case a blackish residue consisting of a carbide of iron was left; in the case of the cold rolled and annealed disks, the carbon in this residue corresponded pretty closely with the total carbon present; but in the hardened disk only one-sixth of the total carbon was found in this residue. In the second series of experiments, the action of various strengths of bichromate solution on cold rolled steel is studied, and it is proved that, if the oxidising solution be not too strong, a residue consisting of a definite carbide Fe_3C is left, and that the carbon is therefore not simply diffused through the mass, but exists as a definite compound capable of resisting the action of a solvent which rapidly dissolves metallic iron.—On the spectrum of beryllium with observations relative to the position of that metal among the elements, by W. N. Hartley. From a photographic study of the spectrum, the author concludes that beryllium is the first member of a dyad series of elements of which in all probability calcium, strontium, and barium are homologues.

Linnean Society, April 19.—Sir John Lubbock, Bart., president, in the chair.—Messrs. T. W. Coffin, F. H. Collins, C. D. F. De Lanne, D. Morris, J. Jardine Murray, and Hon. J. B. Thurston were elected Fellows of the Society.—Mr. J. Britten exhibited and made remarks on specimens of *Arum italicum* from Torquay, South Devon.—Mr. G. F. Angas showed several vegetable products from the Island of Dominica, among others an unusually large seed-pod of *Cassia fistula*, and other examples of Leguminosæ, also Polyporus fungi from the Roseau Falls.—Mr. F. V. Dickins called attention to a Japanese work issued by the University of Tokio, giving descriptions and illustrations of plants grown in the Botanic Gardens of Koishkikawa.—A paper was read by Sir John Lubbock on the sense of colour amongst some of the lower animals (vol. xxvii. p. 619).—There followed a communication by Prof. P. T. Cleve of Upsala, on the diatoms collected during the Arctic expedition of Sir George Nares.—The Rev. A. E. Eaton gave a digest of an extensive monograph of the Ephemeridæ or Mayflies, part i. In this the subject is prefaced by an historical account and general view of the group; the genera are defined, and a

[1] Nearly twenty years ago I observed, among other changes of diathermic position, the reversal of bisulphide of carbon and chloroform, when the pale blue flame of a Bunsen burner was the source of heat. When, for example, the rays issued from a luminous jet of gas, the absorptions of the bisulphide and of chloroform were found to be 9·8 and 12 per cent. respectively; whereas when the Bunsen flame was employed, the absorptions of the same two substances were 11·1 and 6·2 per cent. The cause of this reversal doubtless is that in the Bunsen flame hot carbonic acid is the principal radiant (*Phil. Trans.*, 1864, p. 352).—April 6.

tabular conspectus of the present known species indicated.—A paper was read on the joint and separate work of the authors of Bentham and Hooker's "Genera Plantarum," by George Bentham.

Zoological Society, April 17.—Prof. W. H. Flower, LL.D., F.R.S., president, in the chair.—The Secretary read a report on the additions that had been made to the Society's Menagerie during the month of March, and called special attention to three Sirens (*Siren lacertina*) from South Carolina, presented by Dr. G. E. Manigault, C.M.Z.S., and to an American Teetee Monkey of the genus *Callithrix*, which it was difficult to determine satisfactorily in its living state, but which was certainly new to the Society's Collection.—Prof. Flower, F.R.S., gave an exposition of the systematic classification of the Mammalia which he had recently prepared for use in arranging the specimens in the Museum of the College of Surgeons, and in a treatise on the subject of Mammals in the "Encyclopædia Britannica."—A communication was read from Mr. W. L. Distant, containing the first of a series of contributions to an intended monograph of the Homopterous family Cicadidæ. In the present paper the author gave the results of an examination of the Cicadidæ contained in the Dresden Museum (including the specimens collected in Celebes by Dr. A. B. Meyer), and added the descriptions of other species belonging to the collections of Dr. Signoret and the author. Eleven species were described as new from various localities.—Mr. Sclater read a second paper on the birds collected in the Timor Laut or Tenimber group of islands by Mr. H. O. Forbes, based on additional specimens lately received. The avifauna of the group, as indicated by Mr. Forbes's collection, contained 59 species, of which 22 were peculiar to these islands.—A communication was read from Mr. F. Moore, F.Z.S., containing the first part of a monograph of the butterflies belonging to the groups *Limnaina* and *Euplœina*.

Physical Society, April 14.—Prof. G. Carey Foster in the chair.—New Members: Mr. W. F. Smith, Mr. George Forbes, M.A.—Mr. W. Lant Carpenter read a paper on science demonstration in Board schools, in which he showed the drawbacks of the present system of leaving science to be taught by the other masters, and pointed out the marked advantages of the system followed in Birmingham and Liverpool, where skilled lecturers are appointed to go from school to school, and provided with an assistant demonstrator and proper apparatus. Mr. Carpenter advocated the extension of this system to London and the country in general. He also showed the evil of the present system of cramming for examinations. Dr. W. Carpenter pointed out the advantages of object lessons in training the minds of children. Dr. J. H. Gladstone stated that much had been done in London to introduce object lessons, and that under the Mundella code science would be taught in all Board schools to all the children, who, however, might have the opportunity of choosing between science and literature. Mr. W. Baily, Prof. Foster, and Prof. W. Chandler Roberts, also advocated the system of special science teachers.—Prof. Roberts then took the chair, and Mr. Glazebrook explained a new polarising prism which he had devised to prevent displacement of the pencil of rays. He also showed how the curved diffraction-gratings of Prof. Rowland do not always give perfect definition, and calculated the aberration of the rays.—The Secretary then read a paper by Mr. W. H. Stokes and Mr. A. E. Wilson on experiments on the viscosity of saponine. When a disk is rotated in water, the resistance to its motion is greatest when the plate is immersed a little below the surface; but with saponine the viscosity is greatest when the disk is not wholly, but only partially, immersed below the surface.

Entomological Society, April 4.—Mr. J. W. Dunning, M.A., F.L.S., &c., president, in the chair.—The death of Prof. P. C. Zeller of Stettin, one of the Honorary Members of the Society, was announced and commented upon.—Two new Members were elected.—Mr. W. F. Kirby exhibited specimens of *Acridium succinctum*, Linn., one of the most destructive species of migratory locusts in India.—Prof. Westwood mentioned that a Myriopod, *Polydesmus complanatus*, Linn., had lately been erroneously announced to be the cause of the potato disease.—Rev. A. E. Eaton exhibited a patent revolving object-holder used by mineralogists, which seemed likely to be useful to entomologists also.—Mr. E. A. Fitch exhibited galls of *Cecidomyia violæ*, Loew., and of *Aploneura lentisci*, Licht.—Sir S. S. Saunders read a short paper on the classification of the germ-feeding races of fig-insects.—Mr. H. Goss exhibited specimens of *Pimelia angulata*, Fabr., from the temple of the Sphinx at Ghizeh.—Papers read:—On a small collection of Clavicorn *Coleoptera* from North Borneo, by Mr. A. S. Olliff; Descriptions of new genera and species of *Hymenoptera*, by Mr. P. Cameron; and notes on new or little-known species of *Hymenoptera*, chiefly from New Zealand, by Mr. W. F. Kirby.

Edinburgh

Royal Society, April 16.—Mr. Murray in the chair.—Mr. Sang read a paper on some properties of the curve of simple flexure, of which he gave neat geometrical demonstrations. A simple construction was given for finding the radius of curvature at any point and so affording a ready means for tracing the curve. The related theorems in pendulum motion were also given.—Dr. Knott communicated the results of electrometer measurements of the resistance of electrolytes, which had been carried out lately in the Edinburgh University Laboratory. The method seemed capable of giving fairly accurate values.—In a note on the electrical resistance of hydrogenised palladium, Dr. Knott gave 1·51 as the ratio of the resistances of the fully-charged and pure palladium, the increase of resistance being very nearly proportional to the charge for smaller charges. It was also noted that the electromotive force between palladium and platinum dipping in dilute sulphuric acid was greatly increased for a slight charge of hydrogen, falling off again very markedly as the charge reached its maximum.—Dr. Macfarlane, in a note on plane algebra, or double algebra, as De Morgan named it, demonstrated with facility certain theorems that ordinarily require considerable algebraic manipulation.—Prof. Tait presented a continuation of his theoretical investigations on heat conduction in heterogeneous bodies, as modified by the Peltier and Thomson effects, and gave the result of his investigation of the thermoelectric position of pure ruthenium. On the diagram this metal lies below iridium, to which it is in other thermoelectric respects very similar.

Berlin

Physical Society, April 6.—Dr. Aron reported on the accumulators, on which he has been making experiments for several years past. Even before M. Faure's discovery, at the time when M. Planté announced his first essays with the secondary batteries, Dr. Aron was endeavouring to determine a convertible electric element which, being theoretically possible, might also be available for practical purposes. He first of all tried to make the Daniell chain convertible by using, instead of the two amalgamating fluids, hydrate of soda and sulphate of copper which do not amalgamate, but without success. Like many others he repeatedly tested Planté's already published statements regarding convertible cells of plates of lead immersed in diluted sulphuric acid, and which had to be charged in a very definitely prescribed way, but without any certain results. The cell sometimes became charged and discharged alternately, at other times not. He accordingly tried plates of lead which had been previously crystallised by corrosion, and these he found far more reliable. He therefore constructed accumulators of plates of lead in sulphuric acid to which some nitric acid had been added. Although more certain in their application, these were by no means equal to the practical requirements. The favourable results of the corrosion, as regarded the crystalline surface, a point also confirmed by Planté himself, was explained by Dr. Aron, who attributed it to the disintegration of the metal. He therefore tried to increase the effect by using lead-sponge, but without result. At that time he also thought of red lead, but made no experiments with it, because he knew of no means of fixing this powder to the lead plate conductor. It is now known that M. Faure simply spread the red lead on the plates, and thus produced his powerful accumulators possessing great storage capacity. When this became known, Dr. Aron carried out an extensive series of similar experiments in order to test its practical value, and even increase it. For the latter purpose he introduced a substantial improvement by attaching the red lead with collodium, which in the practical application of the chains is of course out of the question. But as regards their practical utility the accumulators have fallen far short of the hopes generally entertained of them. The main difficulty lies in the thin plates of lead which, when thickly covered with red lead, although very effective, become corroded and useless after being once used, while thick plates, by the formation of sulphate of lead, are rendered ineffective. As to the theory of accumulators, to rightly understand it, it is very important to bear in mind the

fact established by Messrs. Gladstone and Tribe, that in the cell, consisting of two plates in diluted sulphuric acid, the electric current changes the sulphate of lead generated at the positive pole into peroxide of lead, $PbSO_4 + H_2O + O = PbO_2 + H_2SO_4$, whereas at the negative pole the sulphate of lead is simply decomposed into sulphuric acid and disintegrated lead. Hence, after charging, the cell consists of Pb | H_2SO_4 | PbO_2 | Pb, a combination which yields a very powerful discharge, available also for a protracted period. To this theory it has been objected that at the negative pole the sulphate of lead cannot be decomposed into lead and sulphuric acid. But Dr. Aron has satisfied himself that, under the influence of the hydrogen beginning to be generated, very thin layers of sulphate of lead become so reduced, thicker layers alone resisting decomposition. The process at the positive electrode being really such as is described by Gladstone and Tribe, the above theory of accumulators may, broadly speaking, be accepted as correct. As regards the peroxide of lead, the speaker pointed out that this combination is admittedly of a brown colour, whereas the substance deposited on the positive plate is black. From a more searching examination of this substance, it resulted that it is not the peroxide, but a hydrate of the peroxide of lead. And Dr. Aron suspects that there is here less question of a hydrate PbO_2H_2O than of a combination of the oxide of lead with peroxide of hydrogen. A series of theoretically interesting isolated phenomena may possibly be produced by following up the processes here in question. But in the present conditions Dr. Aron holds the practical application of the accumulators to be hopeless.—Prof. Neesen briefly described a slight improvement in the quicksilver air-pump, illustrating it with a diagram.

PARIS

Academy of Sciences, April 23.—M. Blanchard in the chair.—The death of Prof. Roche of Montpellier, Correspondent in Astronomy, was announced. (A report on his work by M. Tisserand is inserted in *Comptes Rendus.*)—A new method for determination of the right ascension of polar stars, and of the inclination of the axis of a meridian above the equator (continued), by M. Lœwy.—On some relations between the temperatures of combustion, the specific heats, the dissociation, and the pressure of explosive mixtures, by M. Berthelot.—Note on the inland African sea, by M. Cosson.—On a manner of determining the angle of position of a point of the surface of a star with the aid of a horizontal telescope, by M. Trépied.—On the use of the horizontal telescope for observations of solar spectroscopy, by M. Thollon. His apparatus is essentially a horizontal telescope deprived of the tube and reduced to its most simple expression. It is more easily managed than an equatorial. The mirror used is guided by the two hands, and the solar surface is explored at will. The author shows how he solved the difficult problem of determining position.—Determination of a particular class of surfaces with plane lines of curvature in a system, and isotherms, by M. Darboux.—On the reduction of ternary positive quadratic forms, by M. Minkowski.—Law of periods (concluded), by M. de Jonquières.—On a relation of involution, concerning a plane figure formed of two algebraic curves, one of which has a multiple point of an order of multiplicity inferior by unity to its degree, by M. Fouret.—Study of infra-red radiations by means of phenomena of phosphorescence, by M. Becquerel. He indicates the results of his method with telluric bands, the absorption spectrum of water and of some earthy metals, and the emission spectrum of metallic vapours.—On the specific heat of some gases at high temperatures, by M. Vieille. He verifies, for the gases H, O, N, and CO, the identity of the molecular heats with constant volume up to 2700°. The measurement of pressures leads him to attribute to certain reactions temperatures much higher than have been supposed practically realisable.—On the variation of indices of refraction of water and quartz under the influence of temperature, by M. Dufet. He indicates a new application of Talbot's fringes in measurement of this variation. The number for quartz is almost identical with that obtained by M. Fizeau.—Experimental studies on the production of vowels in whispered speech, by M. Lefort. Air is blown into a cavity of variable capacity, open and closable at the upper part. The sounds characteristic of vowels are thus produced. The author claims to prove that the vowels are not timbres (as generally taught); they are notes of different heights of the instrument of speech (quite distinct from the vocal instrument). Various timbres may be communicated to them by action of the muscles of the organ of voice.—On the liquefaction of nitrogen, by MM. Wroblewski and Olszewski. Nitrogen cooled in a glass tube to − 136° C., and under a pressure of 150 atm., does not liquefy. On sudden release there is tumultuous ebullition. Gradual release, not passing 50 atm., yields the liquid, clear and colourless, with a distinct meniscus; it evaporates very quickly. The liquefaction of CO under like conditions on April 21 was announced.—On iodised apatites, by M. Ditte.—Action of water on Theil's lime, and the existence of a new hydraulic compound, *pouzzo-portland*, by M. Landrin. The composition of this compound is silica 44·55, lime 55·45. It is the principal element of all Theil's compounds.—On some phenolic derivatives, by M. Henry.—Jurassic Echinida of Algeria, by M. Cotteau. Of the 47 species found, 28 occur in Europe about the same stratigraphic levels. Some curious species peculiar to Algeria are noted.—Clayballs of Macaluba, by M. Contejean. These were found (of all sizes from a cannon-ball to a boy's marble) in the dried bed of a ravine, near the mud volcano named. They are of coarse clay, with small crystals of gypsum, giving a rough surface. It is thought they are formed by the autumn rains, and are dissolved by the heavier winter rains.—The perception of white and of complex colours, by M. Charpentier. His curves show, *inter alia*, that what artists term warm colours are distinguished from a colourless ground *more* easily than white, the cold colours *less* easily.—On the functions of pyloric appendices, by M. R. Blanchard. These appendices digest effectively cooked starch, less effectively raw starch, and transform albuminoids; as they do not effect emulsion and decomposition of fats, they are but imperfect representatives of the pancreas.—On the bite of the leech, by M. Carlet. He detached the animal from the shaved skin of a rabbit at different stages. Suppose a scarifier, with three toothed and equidistant blades withdrawing from one another while they press into the skin, and operating several times successively in the same place: this gives a pretty exact idea of the mechanism.—Comparative study of the bacteria of leprosy and of tuberculosis, by M. Baber. The differential properties indicated by Koch do not, he holds, exist; but there are others, bearing on chemical and molecular reaction, on form, and on arrangement in the tissues.—Influence of sensitive (nerve) roots on the excitability of motor-roots, by M. Canellis. Section of the sensitive root increases considerably the excitability of the motor nerve.—Immunity of workers in copper during the last epidemic of typhoid fever; confirmation of anterior observations, by M. Burq.—Influence of altitudes on phenomena of vegetation, by M. Angot. The harvest-time for inter wheat is retarded in France on an average four days where the altitude is increased about 100 metres.

EDUCATION IN THE UNITED STATES

United States Report of the Commissioner of Education for the Year 1880. (Washington: Government Printing Office, 1882.)

ANOTHER valuable survey of education in the United States has been published, relating to the year 1880; a survey made by the Bureau whose duty and purpose, it is laid down, shall be "to collect statistics and facts showing the condition and progress of education in the several States and Territories, and to diffuse such information respecting the organisation and management of schools and school systems and methods of teaching, as shall aid the people of the United States in the establishment and maintenance of efficient school systems, and otherwise promote the cause of education throughout the country." The Bureau has no authority, it tells us, and seeks none, to interfere with school organisation, but aims to report institutions precisely as they are; and the variety of experiments tried in the States, which in kindred and spirit of government are so close to our own, must make this publication a repertory of experiences of the utmost value to the English educationalist.

The following is the immense provision made for education in the United States:—For public or common schools, every sixteenth section of public land in the older States, and every sixteenth and sixtieth in the newer ones: calculated to equal nearly 68 million acres; for seminaries or universities, two townships, or 46,080 acres in each State, and in some instances a greater quantity. An additional grant in 1862 of 30,000 acres for each senator which each State was entitled to send to Congress was awarded for the establishment and support of agricultural and mechanical colleges, amounting to 9,600,000 acres. Total, 78 million acres!

Yet, with this immense provision, the Old World difficulty is making itself felt strongly now in America as population increases, which was not foreseen when each State laid it down that education should be provided for every child, viz. that a considerable proportion of that population now will not avail themselves of this education. In very few States is the increase in scholars nearly in proportion to the increase in population, and our Report gives serious confirmation to the alarming statistics lately brought forward by the Rev. Joseph Cook in his Boston lectures. Private effort to attract children to school by providing them also with clothing is said now to be "occupying a very important place." Like other signs of "Progress and Poverty" which Mr. Henry George urges so warmly, there is now enough truancy and absenteeism from school to become a serious hindrance to education. In some New England cities truant officers are appointed, but in other cases the popularity of education without class-feeling allows the important business to be left in the hands of the police.

Cities (under which definition are enumerated 244 municipalities of above 7500 inhabitants) contain one-tenth of the teachers and one-sixth of the school population, and expend more than one-fourth of the money. "While the municipal systems of the United States are more defective, more assailed, and doubtless requiring greater efforts to reform them than any other part of the civil machinery, the city school affairs are in the main well systematised." The Boards of Education are variously constituted in different cities. In some cases the members of the Board are elected directly by the people; in some they are appointed by the Mayor; and in the District of Columbia by the Commissioners.

The powers of School Boards in the United States are in some instances restricted to the care and management of the public schools, while in others they extend to the charge of school funds. In nearly all the cities referred to above, superintendents are appointed—with few exceptions men of superior ability and specially adapted to the work of school supervision, who combine a great deal that is done in England partly by the Boards and partly by the Government Inspector at his occasional visits. They bring to bear more special knowledge of the subject than the former, and give far more time to each school than the latter can.

This Report contains a review of education through the decade, and perhaps the most striking thing is the absence of uniformity in the circumstances and changes in the different States. Thus, in Maine and New Hampshire during the last ten years, and in Indiana during the last year, population has decreased, but the attendance at schools has nevertheless increased. In Rhode Island, New York, and Iowa the reverse has taken place; the population has increased, but school attendance has decreased. In Arkansas a change of system made in the middle of the decade has resulted in a reduction of everything; the reduced number of scholars attending, however, having largely increased again the last year. In New Jersey and Pennsylvania there is an improvement every way; while in Massachusetts the attendance equals the school population. In Virginia the increase in every particular has been great. The Maryland schools only suffer from a decrease in the income for public school purposes.

The Report is very satisfactory as to the difficult matter of educating the coloured race. In 1870, out of 2,500,000 above fifteen years of age less than 150,000 had attended school. At the time of this present Report (1880) there is a total attending school of more than 800,000—over 15,000 of whom are, moreover, attending the higher grade schools. Those of them who are attending normal institutes for coloured teachers manifest great interest in the opportunities for improvement thus afforded. There is still, however, great deficiency of such trained teachers, and the poverty of the country is so great that the schools in rural districts are held in their churches, and the duty of assistance to them is urged by the Commissioner upon the national Government that has made them free. Considerable help has been given to the work among them by the Peabody fund, but the religious denominations of all the States have done most—in fact, five-sixths—of the work. Of 44 normal schools, 29 are under their auspices; of 36 institutions for secondary instruction, 31; 13 of the 15 universities or colleges; and all the schools of theology. But in all the States with mixed population now, except Delaware, Kentucky, and Maryland, school funds are devoted to school population without regard to colour.

In our crowded island we need not refer again to the

other special difficulty of the United States. The scattered population leads inevitably to small schools: in Maine, 1200 out of 4000 had average attendances ranging from two to twelve; this leads, of course, to low pay; and this to low attainments on the part of the teachers, of whom not more than 4 per cent. have had normal training. A great drawback to teachers also is the uncertainty of their tenure of office. In some States the School Committee have no power to hire teachers for more than a year, and engagements are seldom made for a longer time. In others, men are employed for winter and women for summer terms, thus causing an uncertainty in the profession, which must be highly mischievous. It is a feature in American education, that in both elementary and secondary schools more than half the teachers are women. In this respect the United States differs from every other nation; and a fear is expressed lest it may involve the sacrifice of some of the conditions essential to the development of strong self-reliant characters. As the Transatlantic ladies are supposed not to be wanting in these themselves, let us hope that it may not have such an effect; but that it may be said of this arrangement that—

"Emollit mores, nec sinit esse feros."

The Commissioner in his Report says that, "carefully considering the position of woman in the work of education, what she has done, and may do, as a teacher, what her nature and experience may fit her to do better than man, as an officer, inspector, or superintendent, he has favoured the opening of appropriate offices to her in connection with institutions and systems of instruction." He "regrets to say that women have shown more indifference to this opportunity than he expected." There are 227 women's colleges in which every advantage is offered that men have, but they are not popular. Still he points out that since women were elected in 1873 to the Boston School Board, and subsequently admitted to that and other Boards, the employment of them on sub-committees, for which they were best adapted, has been the introduction of a new force; in other words, it is in the line of progress.

The Report urges the desirability of well-trained teachers, more particularly in the case of scientific knowledge. "Such knowledge finds its application in all arts and industries, and in all measures for the preservation of health and life, and it offers the only means of dissipating the fears and superstitions, and correcting the foolish practices arising from ignorance of the phenomena and laws of nature." It points out also that the general Government is doing more in behalf of scientific work and publications than all the other agencies put together.

Partially, no doubt, the result of a feeling making its way among educationists, but partially also a sign of the moderate level of education reached, is the small number (448) in Ohio who learn Greek. A curious mark of changed relations is to be found in the fact, that still fewer (418) learn French; while nearly 100 times the number (40,813) learn German; against nearly 650,000 who learn spelling.

Where the ordinary primary education is good in America, evening schools of elementary grades are less sought after than those of advanced grade, except in cities where there is a large foreign population. In communities, distinguished alike for intelligence and business enterprise, evening high schools are especially appreciated, the most promising artisans and clerks looking to them for the means of continuing their studies.

The peculiarly American institution of summer schools is being turned to admirable use by teachers occupied with regular school duties during the rest of the year, who go with scientific expeditions and to stations maintained by the universities, and profit by the facilities for study and investigation thus offered them in combination with fresh air and change of scene.

There has been scarcely any increase since 1875 in the number of universities or colleges as they are indiscriminately called, but the new States are many of them overprovided with these higher-branch schools, while deficient in the elementary schools at present more necessary. The disproportion between colleges and preparatory schools in certain States may be judged by the report that while Tennessee has twenty-one colleges, Massachusetts with a larger population reports seven. The former State has two preparatory schools; the latter twenty-three. Under such circumstances it is not strange that some of these universities or colleges should be doing the work of the lower grade schools, as thirteen are reported as doing only.

In 1871 Arkansas established an industrial university which soon after possessed classical, agricultural, engineering, commercial, and normal courses, and a preparatory department. In various other States similar centres of education in practical subjects were opened, and the variety of subjects and arrangements for teaching them, which are to be found in so many independent centres, will be found very instructive to all who are inquiring about technical education, especially agricultural. Several of these courses are such as have been approved of after varied experiment; an advantage which they have over the schools of science not endowed by the national grant, where the will of the founder has had a contrary effect.

Michigan University has inaugurated an excellent work in providing that a faculty will visit once every year any public high school in Michigan on request of its School Board, and report its condition. "If the faculty shall be satisfied that the school is taught by competent instructors and is furnishing a good preparation for any one or more of the regular courses of the University, then the graduates from such preparatory course or courses will be admitted to the freshmen class of the University without examination, and permitted to enter on such undergraduate course as the approved preparatory work contemplated." This is a method of making the same labour serve the double purpose of inciting the school to efforts, and also of matriculating the University students. The matriculation examinations at so many of these universities were naturally of most various standards, and some approach towards a uniform standard has been made between ten principal colleges in New England.

In the Illinois State University a peculiar government has been tried called "The Students' Government," by which every official was selected or appointed by the president whom they had elected, and all the forms of a Republican Government are gone through; forming an excellent practice to the students and probably raising a good *esprit de corps*.

The comparison of the state of medical instruction at

the present with what it was ten years ago, although showing great improvement, still draws a discreditable picture of what so important a profession is allowed to remain in America; and quite a romantic tale is told of the means by which men getting a living by selling false degrees were brought to justice. The number of the universities and other bodies which claim the right to bestow degrees makes the tracking down such forgeries very difficult.

The business of nursing the sick is rising to its proper position as that of an intelligent assistance to the profession of medicine. Our Report wisely recounts the good results to be gained by student-nurses, though chiefly moral qualities are inculcated.

In the schools of science, the number of students which increased so largely in 1878, but fell off in 1879, has begun to increase again; the number of institutions as well as teachers having increased steadily all the time. Our Report says:—"The multiplication and growth of schools of science has been a marked feature in the recent history of education in America. Either the stimulus given to them by the national aid, or the sentiment which compelled Congress to give help to higher education, has carried forward and deepened the interest in industrial, scientific, and technical instruction. Students are now more frequently choosing lines of study which lead to a life of business activity or to prominent positions in industrial pursuits. Colleges that a few years since held strictly to a rigid classical course are feeling the new impulse and are striving to add to their efficiency by making provision for special instruction preparatory to definite occupations. Men of wealth are endowing schools of science and technology more richly than other institutions; for they believe that the practical education which has now come to the front will do more than anything else to promote the industry and prosperity of individuals, and to utilise the resources of the nation."

The requirements for admission to the scientific department of colleges and schools of science are not so great as to classical collegiate courses.

It is rather curious that the study of Latin is allowed to be dropped in a law school of Harvard; but the following remarks made upon the value of law schools, as compared with that of articling pupils to lawyers, may well be applied not to them only but to all technical instruction:—"In schools systematic training is received. Less opportunity is afforded for desultory and spasmodic reading. Regular habits of study are required. Examinations to be passed give steadiness and thoroughness to the work. Companions make emulation. The desire for the respect of the professors is a further stimulus to faithfulness, and they are ready to aid in the understanding of intricate questions. Underlying principles are given an attention which corresponds to their relative importance."

Forestry is taught in some of the higher institutions, with plantations of trees arranged in their natural orders; and its value is pointed out, both as a branch of knowledge to the students, and also as adding to the knowledge of the range of possible and profitable cultivation of many species.

A system of teaching the deaf and dumb to read from the lips of others instead of the old finger reading is described as wonderfully successful and fast gaining ground.

Not a small advantage will science gain if the system of making full inquiries into the antecedents of every case of the above, as also of blindness, is patiently and thoroughly carried out. Some generalisations have already been made with regard to the latter. In the case of 100 feeble-minded scholars their weakness is traced to consumption in their stock. An inquiry into colour-blindness in the Boston schools leads to the recommendation that a systematic process of giving instruction in colour, its names, and shades, should be introduced into primary schools.

The importance of reform schools is steadily and strongly upheld. The needs of their inmates are wisely consulted by an education more moral than intellectual being instilled into them, and by a knowledge also of some method of gaining a living when dismissed being carefully given to them. The better feelings are drawn out and encouraged by a system of rewards for all good conduct, instead of only punishments for bad. Two curious observations are recorded: one is, that working among flowers has a softening tendency upon such characters; and the other, that prisoners are, in general, singularly short of mathematical ability.

The increase in the number of free libraries since the previous year's Report alone nearly equals the entire number of them in England, making a total nearly reaching 3000. Though many of these are very small and to be compared with school libraries here, yet they average all through 4000 volumes in each. A large increase also is noticeable in Kindergarten schools, in schools for nurses, in deaf and dumb, orphan, and reform schools.

The Bureau is indebted to private enterprise for a competition on the subject of schoolhouse plans organised during the year by the "Plumber and Sanitary Engineer." It has drawn forth from the committee of award a sketch of the qualifications they believed to be necessary for a public school building in a large and densely populated city. They lay down ten primary requisites which every plan ought to contain; and the Commissioner hopes that an impulse has been given by their report, which will not be lost or wasted.

Education, we are told, has become in every section of the country a matter of more active public interest than usual. City and country papers have given a place in their columns to the subject, besides periodicals discussing them. It is rather curious to us in aristocratic England to find not selfishness and stupidity only but demagoguism also charged with creating discouragements! W. O.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*

[*The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to insure the appearance even of communications containing interesting and novel facts.*]

The Microphone

It is probable that the writer of the note at p. 588 has not had an opportunity of seeing the paper of mine to which he refers, and an abstract of which is given at p. 376 of the present volume of Nature.

The adhesion between metallic contacts consequent upon the passage of a current has been carefully investigated by Mr. Stroh, who observed it in the case of all of a great number of metals with which he experimented. My first observations on the subject (one of which is mentioned in the paper) were made with the refractory metal platinum, and not with bismuth, as the writer of the note seems to infer; and though Mr. Stroh's explanation—that the adhesion is due to fusion—is quoted, I express no opinion of my own on the matter. Whatever may be the cause, it seems evident enough that such adhesion must necessarily be detrimental to the perfect action of a microphone, though I am not aware that attention has been previously directed to this point.

It is not correct to attribute to me the opinion, as stated in the note, "that the heat generated by the current plays an important part, for in carbon this reduces the resistance, whilst in metals it increases it." On the contrary I give reasons for believing that at least a moderate degree of heat increases the resistance of loose carbon contacts. Increased *current*, however, is accompanied by diminished resistance, and while I am not prepared to say that heat plays no part whatever in the matter, it appears to me probable that the effect is mainly owing to some other incident of the stronger current, *e.g.* greater difference of potential.

My experiments on metals were not, as the writer supposes, entirely confined to bismuth. More than a hundred observations were recorded of the resistance of platinum and copper contacts under different conditions, and some of these are referred to in the paper. Owing, however, to the low specific resistance of these metals, the methods which I had applied with success in the case of carbon were found to be unsuitable, and the results obtained, though not on the whole inconsistent with those yielded by bismuth, were unsatisfactory and inconclusive. Bismuth was chosen for the bulk of the experiments, principally on account of its bad conductivity, which renders changes in the resistance of the contact easier of observation; but since it was my object to contrast the behaviour of metals with that of carbon (which is infusible), its ready fusibility is another advantage. If I had desired to make a good metallic microphone, I should probably have thought with the writer of the note that bismuth was "the very metal which ought to have been avoided." But for experiments conducted with the object of ascertaining the causes of the generally recognised fact that metals, as a class, are inferior in microphonic efficiency to carbon, it is evident that the metal which gives the poorest microphonic effects is *the very one which ought to be selected*, on account of the probability that with such a metal these causes would be most conspicuous.

As a matter of strict scientific exactness I agree with the writer that "no conclusion of any value as to metals in general can be drawn from experiments on bismuth alone." But since the physical properties with respect to which bismuth differs from carbon, and which have any probable connection with microphonic action, seem to be common in various degrees to all metallic bodies, I venture to predict with tolerable confidence, that if the experiments described in the paper are repeated with suitable apparatus, it will be found that all the conclusions arrived at with regard to bismuth (as summarised in the abstract before referred to) are also true to a greater or less extent for any other ordinary metal. SHELFORD BIDWELL

Wandsworth, April 22

[The necessary brevity of the note to which Mr. Bidwell refers precluded lengthy quotations. At the same time it was only natural to draw attention to the weak point in Mr. Bidwell's argument, namely, that the behaviour of the metals generally could not with any certainty be argued from observations made, as Mr. Bidwell admits, on the very metal which for practical ends ought to be avoided. It is greatly to be wished that Mr. Bidwell will so far further improve the capabilities of his apparatus as not only to be able to get conclusive results with other metals, but also so as to enable him to say why his apparatus gave results that were unsatisfactory and inconclusive with good conducting metals such as platinum and copper.]

The Soaring of Birds

FOR more than twenty years I have watched with admiration the soaring of the black vulture of Jamaica (*Vultur aura*). When once well up in the air it rarely moves its wings, except to change the direction of its flight. It can soar whenever there is even a light wind.

I entirely concur with Mr. Hubert Airy in the main point of his general conclusion, as given in vol. xxvii. p. 592. "Variations in the strength and direction of current" can, as he says, be so "utilised" by birds as to enable them to soar. But a high wind is not necessary; and a downward current, even when approaching the perpendicular, may, if of sufficient velocity, be utilised.

Whenever there is a wind there will be ascending and descending currents in some places. This will be so even in a level plain which presents no considerable obstacles, such as trees or buildings, to the stream of air. The plain will be bounded by hills of varying height, and it will vary in breadth. A stream of water would merely flow more rapidly through the narrower channels; but a stream of air, being highly elastic, will also rise and fall, and it will have its eddies in planes more or less inclined to the horizon, and will often acquire a rolling motion. Assuming the existence of ascending and descending currents, the soaring is a very simple matter. *The bird contrives to remain much longer in the upward currents than in the downward.* It will glide along the ascending side of a wave of air and cut across the descending side. It will make many spiral turns in an ascending current of sufficient amplitude. I have often seen the vulture ascend thus for more than 2000 feet, keeping near a steep mountain side. If the bird encounters a descending current, of which it is instantly aware through the diminished pressure on its wings, it will either wheel to the right or left to get out of it, or, altering the pitch of its wings, will descend swiftly so as to acquire the necessary impetus for a rapid escape, or will do both.

It can also avail itself of inequalities in the velocity of horizontal currents flowing parallel to one another at the same elevation. The bird, let us suppose, encounters a strong horizontal current, as warm as it is rapid, issuing from a mountain valley or a cutting through a forest. Instantly throwing its wings into a plane nearly vertical, it receives on them the force of the current, and in a few seconds acquires its velocity. Pitching its wings also for a downward flight it shoots quickly through the current, having acquired a speed more than sufficient for the recovery of its original elevation. If the current be very strong and very narrow, it need not be horizontal, but may approach the perpendicular. The bird will not remain in it long enough to be carried far down, while it acquires an impetus much more than compensating for the slight loss of elevation. It must be remembered that when the bird is gliding at a high rate of speed, the resistance of the air, through its inertia, to any movement except in the plane of the wings, almost equals that of a solid body, and a change of direction causes a very slight loss of momentum.

What rapidity of currents is necessary for soaring must depend in great measure on the structure of the bird. The vulture is, I believe, comparatively heavy, but I think that, having once acquired speed by a short and steep descent, it can glide through still air (or at right angles through air having a uniform horizontal notion) at the rate of twenty miles an hour, descending not more than one in twenty. If, therefore, the bird could be always in an upward current of only one mile an hour, it could maintain itself in the air. A gentle breeze of ten miles an hour, with one mile an hour of ascent—and a much steeper ascent than this must be frequent enough where there are hills—would suffice to sustain the bird; and as an average of ten miles an hour implies local or occasional gusts of greater velocity, of which the bird knows how to avail itself, it could ascend in such a current, and so be able to work to windward. If besides hills of moderate inclination, there are also trees, walls, houses, the air will often be driven upwards, vertically or nearly so, with as great or even greater speed than that of its average horizontal movement; and of this upward movement the birds avail themselves most skilfully. I have frequently seen the vultures working their way thus against a high wind. Their movements are very irregular. Sometimes, to avoid a violent gust, they will drop almost perpendicularly to within a yard or two of the ground, and shooting abruptly sideways with the high velocity gained by the drop, will get into an upward current in which, if ample enough, they will wheel, or else will cross and recross it, till they have gained a sufficient elevation, and then, taking advantage of a lull, will glide to windward.

With a breeze of only five miles an hour, there will be in many places upward currents of high inclination caused by the usual irregularities of surface. Keeping sometimes in these and sometimes in currents more slightly ascending, for, say, two-

thirds of its time, and utilising also, as I have above explained, the more rapid of the descending currents, the bird can more than sustain itself. It can at will glide to windward at the rate of fifteen miles an hour against the breeze, losing of elevation only one in twenty.

R. COURTENAY

L'Ermitage, Hyères (Var), France, April 28

Flight of Crows

I CAN corroborate the observation of Mr. Murphy as to the oblique flight of crows. When I have seen them so flying there has always been a cross current, and they have merely kept their heads a little to the wind.

Cambridge THOS. MCKENNY HUGHES

Sheet Lightning

Du choc des opinions jaillit la vérité. I still adhere to your assertion that sheet lightning is not, at least in most cases, the mere reflection of a common but distant storm. On the highlands of Ethiopia, in the years 1842 to 1848 I was diligently engaged in investigating the electrical phenomena so frequent in that region. The details of my observations were printed in 1858 by the French Institute, and I have published again my results in my "Observations relatives à la Physique du Globe" (Paris, 1873). The following cases may be of interest :—

Near the zenith eight successive flashes of lightning were seen 21 seconds before their thunder, which lasted exactly 12 seconds. Another day it lasted 24·4s. thirty successive times, and, as previously, without any rain. My greatest observed interval was 111·2s., corresponding to a distance of 38,500 metres, &c.

I have seen more than once straight or zigzag lightning unaccompanied by thunder. One afternoon it went to and fro *twice* between two horizontal cloud banks, and ended in sheet lightning which illuminated, not the lower dark bank, but only the under surface of the upper cloud. I have observed frequently thunder without lightning and lightning without thunder.

When in Adwa I recorded silent sheet lightning towards Gondar, 240 kilometres distant, where a violent storm was raging at the same time. Before leaping to a hasty conclusion, let us hear a case bearing pointedly to the opposite opinion : in 1845, at Saga (latitude 8° 11′), a semi-transparent fog which had mantled over the valley, and could not be more than 3500 metres distant, gave out a flash of sheet lightning without thunder.

Although my numerous observations have given me a strong bias in favour of your opinion, I do not wish to impose it on reluctant philosophers, but suggest the following system to clear up the question :—Let two observers, A and B, 40 or 50 miles asunder, mention instances of lightning seen in each other's true bearing. If they can also secure the help of a third observer located on or near the straight line from A to B, and who can watch in two opposite directions, many important results may be obtained.

Paris, May 5

The American Trotting-Horse

MR. BREWER's memoir on the evolution of the breed of the American trotting-horse (NATURE, vol. xxvii. p. 609), and the statistical tables that accompany it, are full of interest, but I only propose now to concern myself with the latter, which may be easily and usefully discussed by employing a statistical method that I have long advocated. In explanation I will begin by extracting the final terms of four of the lines of his table, as follows :—

Year.	2.27 or better.	2.25 or better.	2.23 or better.	2.21 or better.	2.19 or better.	2.17 or better.	2.15 or better.	2.13 or better.	2.11 or better.
1871	99	40	17	12	6	1			
1874		98	40	16	11	5	1		
1877			105	51	19	8	2		
1880				106	41	14	6	2	1

The meaning of these entries are, that in the year 1871 there were 99 horses that could trot a mile in 2 minutes 27 seconds, or less ; that in the same year there were 40 that could trot it in 2 minutes 25 seconds, or less ; and so on. Their significance is that the rate per mile of the hundred fastest American trotting-horses has become 2 seconds faster in each successive period of 3 years, beginning with 1871, and ending with 1880 ; also that the *relative* speed of the hundred fastest horses in each year is closely the same, though their absolute speed differs.

We may read the table in another way. If the number of horses that can run a mile in 2 minutes 27 seconds or less is 99, we may infer without risk of sensible error that the 99th horse in the order of running accomplishes a mile in *that time exactly*, because the 100th horse certainly takes a longer time, and it is statistically incredible that the rate of the 99th and of the 100th horses should differ by more than a barely perceptible interval. For the same reason we may infer that the 40th horse in that same year runs a mile in 2 minutes 25 seconds, and so on. We can now draw curves, and by graphical interpolation find with the greatest facility the mile rate of the horse in *any* order of running in any year that we please to select. I have selected the 100th, 50th, 20th, and 10th horse respectively for each year beginning with 1874, when we are informed that the returns first begin to be accurate, and have thrown the results into the following simple table. The curves obviously required a little smoothing here and there, and in three or four places the readings have been thereby modified by one or two tenths of a second. Otherwise they are given directly from the rough plottings.

Number of Seconds and Tenths of Seconds in Excess of Two Minutes that are required for Running One Mile by the Horses whose Order in the Rate of Running in each Year is given at the Top of the Columns

Year.	100th.	50th.	20th.	10th.
1874	25·1	23·4	20·5	18·8
1875	24·1	22·5	19·9	18·2
1876	23·5	21·6	19·5	17·7
1877	22·9	21·0	19·0	17·4
1878	22·1	20·2	18·5	17·0
1879	21·3	19·6	18·0	16·6
1880	20·8	19·3	17·6	16·0
1881	20·4	18·8	17·2	15·7
1882	19·9	18·4	17·0	15·4
Anticipated 1890	16·8	15·5	14·4	13·4

Mem.—The first horse runs the mile in about 5 or 6 seconds less than the tenth horse.

It will be found on plotting the figures in the vertical columns into curves, that they run with much regularity and differ little from straight lines. The general conclusion to be derived from them is that the improvement of the running shows as yet little tendency to slacken, though no doubt if the number of horses bred for trotting ceased to increase yearly at the same large rate as hitherto, it might do so. Supposing, however, the conditions to be maintained, I should anticipate that in 1890 there will be about 15 horses that will run a mile in 2 minutes 15 seconds or less, and that the fastest horse of that year will run a mile in about 2 minutes 8 seconds.

FRANCIS GALTON

The Shapes of Leaves

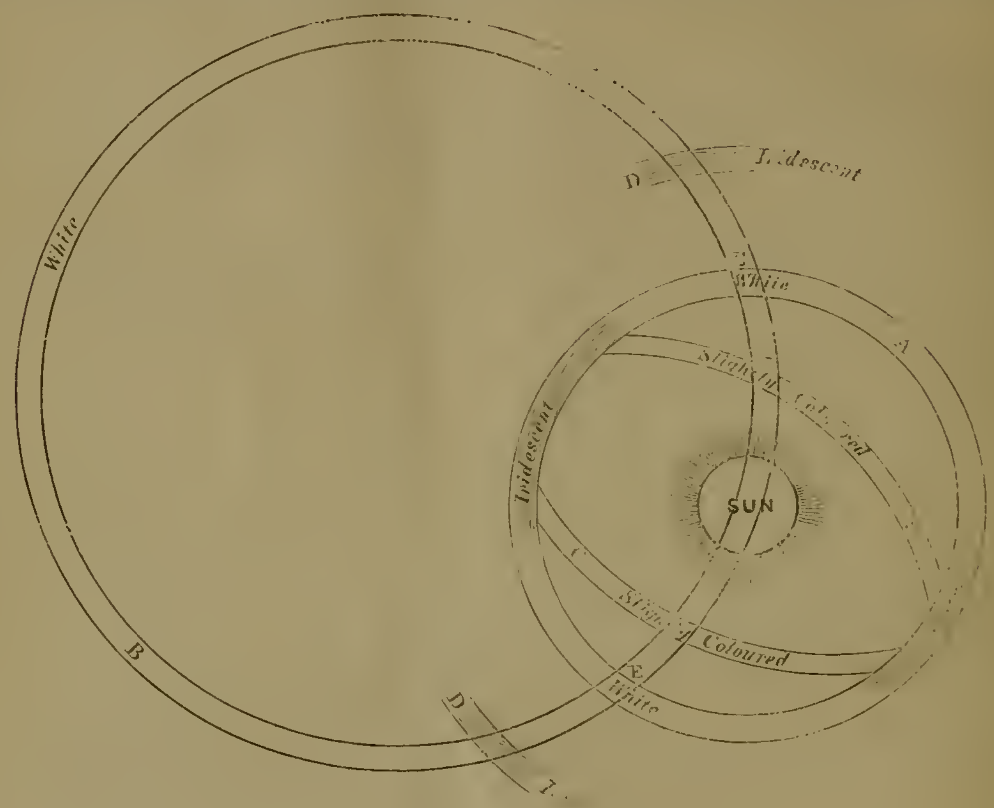
MR. GRANT ALLEN's papers in NATURE will evidently serve to direct attention to a most interesting subject which hitherto appears to have been much neglected. Every contribution of observed facts may tend to throw further light upon it, and I therefore venture to remark that one cause of the frequently filiform character of the leaves of water-plants appears to be the elongating action exercised upon the cells by the pressure of a rapid current of water, since it is obvious that growth must take place in the direction of the least resistance. With a radiate-veined leaf the tendency must be towards lateral pressure, which would compress and elongate, and so give a linear form to the leaf-cells. I have been much interested to observe that on the seashore, in places where Fuci are exposed to this action by the ebbing tide, as when growing on the edge of a large boulder or hanging over its sides, the fronds and even the receptacles become unusually elongated.

On the other hand, where a freshwater stream mingles with the salt water in pools left by the tide, and the endosmotic action of the water set up by its reduced density is greater, the algæ become broader if flat, or of more inflated character if tubular. This is well seen in *Dumontia filiformis*, *Enteromorpha intestinalis*, and *Chondrus crispus*. The influence exerted by the character of the surrounding medium and pressure may also be observed in that interesting genus of freshwater plants, Callitriche.
E. M. HOLMES

Solar Halo

I BEG to forward herewith diagram and remarks of solar halo as observed here to-day, thinking it may be of interest, being an unusual phenomenon. The cause depends upon many circumstances necessary for such observations, chiefly a calm reflecting surface of water in front, behind, and around the observer, making their appearance local as well as unfrequent.

The halo marked A, caused by the sun's rays passing through the thin cirri, was reflected from the surface of the water on the English Channel side of the island, producing the large white halo B, and passing over the sun's centre, the non-concentric arcs C being most probably reflected from the harbour side, the bright iridescent arcs at D on the large white halo B being the reflected crossings of the two halos at E. I have fixed the points of the zenith and due south horizon as approximately as possible; the observer facing due south, the iridiscent arc D was nearly



Solar Halo as observed at Portland, Dorset, April 28, 1883.

vertical, and about the same distance from the sun's centre to the estimated centre of large halo B, viz. 12°; the diameter of halo B was a little over double that of A.

Latitude of Verne ... ... 50° 32′ 86″ N.
Longitude of Verne ... ... 2° 23′ 40″ W.

Altitude of highest point of Verne 495 feet above sea-level (Ord. B.M.).

Time (local): first observed at 12.20 p.m.; brightest aspect 12.30 p.m.; duration about three-quarters of an hour. Cloud, thin cirri, with cumulo-stratus low in northern horizon. Amount, 9. Wind, S.
E. CARDWELL,
Late Supervisor Meteorological Department, Bombay
Verne Citadel, Portland, Dorset, April 28

I SEND inclosed a diagram of a system of solar halos observed here on Saturday last. If one may credit the oldest inhabitant, the phenomenon is very rare in these latitudes; in fact the ancient mariners frequenting the New Key End declare they never saw the like in all their wanderings.

My attention was first called to it at 12.25 p.m., when it presented the appearance I have depicted; but I am told that earlier in the day a white halo was seen *south* of the sun. The smaller circle had the sun for its centre, round which the sky was of a leaden cast as far as the edge; the fringed portions represent brilliantly coloured partial halos, or coronæ. The larger circle was, as near as I could guess, 40° diam. Its circumference cut the centre of the smaller circle, was brilliantly white, perfectly defined as seen from here, and narrow. I am told that, seen from high ground some four miles from here, it presented the appearance of two horns. The phenomenon lasted after I observed it about an hour, during which time a peculiar haze was drifting over the sky, which, when viewed carefully, seemed to have a hair-like structure, especially when seen passing the bright edge of the larger halo. I may add that the surface wind was southerly, the drift of the haze S.S.E.: a line joining the centres of the circles would point E.N.E. at about one o'clock.
THO. B. GROVES
Weymouth, April 30

Mock Moons

THE explanation of the phenomenon observed on the 16th ult., which is given by "Sm." of Rugby, appears to me to be scarcely satisfactory. According to the usual explanation of halos, parhelia, and paraselenæ, which attributes them to refrac-

tion by prismatic ice-crystals at high elevations, the parhelia always appear on the horizontal parheliacal ring which passes through the centre of the sun, and generally at the intersection of this ring with the vertical halo. The two parhelia must therefore always lie in a line parallel to the horizon, and at the same elevation as the sun itself. The same laws regulate the appearance of the paraselenæ or mock moons. It therefore surprised me to learn that the left-hand mock moon appeared at a greater distance from the horizon than the right-hand one. It seemed to me to be "unaccountably out of place." That the circle should have subtended an angle of 50°, as stated by "Sm.," is in itself unusual. The normal diameter is understood to be from 44° to 47°. Did "Sm." actually measure it? To my judgment it was considerably more than this, but of course mere estimates are not trustworthy. I do not see how a "change of level of the refracting cloud" should alter the position of the mock moons. This must depend upon the relative positions of the moon and the observer's eye. If the cloud is not in the right place no mock moons will be seen. I should be glad of a satisfactory explanation of the phenomenon recorded.

Birstal Hill, Leicester, May 7 F. T. MOTT

REFERRING to a letter from Mr. F. T. Mott in NATURE, vol. xxvii. p. 606, I find that at midnight on April 16 the moon's apparent altitude at Leicester was not more than 26°; so that after allowing for the difficulty of seeing the actual horizon, and taking also into account the breadth of the halo, it seems improbable that the halo observed by Mr. Mott was of unusual size.

I have, however, seen a description somewhere of a *parhelion*—measured with a sextant about the end of last century—which had a semidiameter of 26°. It would be interesting to know whether such irregularities in the dimensions of these phenomena have been accurately ascertained. R. C. JOHNSON

19, Catherine Street, Liverpool

Sun Pillar of April 6, 1883

IT may be of interest to record the various points from which the above phenomenon was seen. I was at St. David's with a party of geological students, and we watched it for some time as we were returning from the coast at sunset.

Cambridge THOS. MCKENNY HUGHES

Fibreballs

I READ with much interest the letters of Prof. G. H. Darwin and "J. H.," NATURE, vol. xxvii. pp. 507, 580. On the coast of South Australia, especially on the Coorong beach, I have seen fibreballs in great quantity; some larger than a cricket ball, and perfectly spherical, hard, and well-matted; others tapering and having the form of an exceedingly long ellipse. I brought home many specimens. These are now in the Wragge Museum at Stafford; and I shall be happy to have some forwarded for Prof. Darwin's inspection.

Fort William CLEMENT L. WRAGGE

Helix pomatia

ONLY a few more lines to say, in consequence of the communication of Mr. Stokoe in your last number (p. 6), that he will find the mollusca in their geological relations treated in the introduction to my work on "British Conchology," vol. i. p. cix. The distribution of *H. pomatia* in this country and on the Continent is noticed in pp. 177 and 178 of that volume, and in the supplement to the fifth volume. J. GWYN JEFFREYS

1, The Terrace, Kensington, May 4

I HAVE found this freely in the hedge-bottoms of Hertfordshire lanes, where the soil was a dark alluvial mould, certainly not cretaceous. I suspect that even in its known localities it is very local. HENRY CECIL

Bregner, Bournemouth, May 5

IN two of the localities mentioned for this snail—Dorking, Surrey; and Woodford, Northamptonshire—there seems some reason to suspect it to be a modern introduction. From 1849 to 1852 I lived within two miles of Woodford, and often found the shells in a small wood known as Woodford Shrubbery. It was commonly said in the neighbourhood at that time that the snails were brought from abroad by the gentleman—I think General Arbuthnot—who had formed the Shrubbery some thirty years before that date.

I also found, many years ago, shells of the same species about the foot of Box Hill, near Dorking, and was told by a former resident in that neighbourhood that the snails were brought from Italy by Mr. Hope, of Deepdene, who was well known in the early part of this century as a writer on the mediæval architecture of Italy. I give the statements for what they may be worth.

Loughton J. C.

Intelligence in Animals

IN addition to the long list of "emotions which resemble human intelligence as occurring in animals below the human species," as given by your correspondent on the authority of Dr. Romanes (NATURE, vol. xxvii. p. 580), and the instance of "benevolence" subsequently cited, I venture to submit the following as illustrating something very like the emotion of contempt.

Until recently our domesticated animals included two cats—one a very fine tabby (a trimmed male) of somewhat morose nature, and a pretty little black cat, a half-bred Persian (a female) of very gentle character. On a noticeable occasion the tabby cat caught a mouse and ate it all up with much relish in a corner of the room. The proceeding was watched with much interest by the black cat from her place on the hearthrug. After the tabby had finished his repast he also took up his place on the hearthrug. The black cat then went over and smelled the spot where the dainty morsel had been devoured. Upon this the tabby cat came up and "boxed" the black cat's ears once or twice, as who should say, "What business have you with my affairs? catch your own mice!" W. R. HUGHES

Handsworth Wood, near Birmingham, May 5

MAY I contribute another case of higher thought in the lower animals. At the farm of Granton Mains, near Edinburgh, an old cat had become blind; her daughter had kittens. The daughter was observed bringing in a sparrow to the boiler-house, where her blind mother and her half-grown kittens were warming themselves: the kittens came up to get the sparrow, but their mother kept them off and gave the sparrow to her mother, and watched whilst she ate it. She was frequently seen to give other food to her blind mother.

My children have a fox terrier bitch, "Dot." Dot loves to kill anything from a cat to a mouse, and sometimes a wild rabbit gets into the garden, and it is a red-letter day for Dot and the children. But the children have also tame rabbits; of course any one who knows dogs will understand that it is simple to teach them not to touch pets—for instance, the cat of their own house. But Dot had a curious case to decide. The children had found a nest of wild rabbits, and two of the tame rabbits (black and white) had made a hole in a bank and there had young ones. This nest was respected by Dot. The children took the young wild rabbits (gray) and fostered them on the tame ones by slipping them into the nest. A few days after this, Dot must have discovered these gray young ones with the black and white. Had she found them anywhere else, one snap, and they were dead; but this was the line she took: she was found at the front door under the porch with one of the young gray rabbits, quite fifty yards from the nest; it was quite unhurt, although it died afterwards, I believe from cold and exposure at the time. Are we to suppose that Dot wished to ask the question, "May I kill this gray one?" DUNCAN STEWART

Knockrioch, May 2

THE SOLAR ECLIPSE OF 1883

THIS eclipse, as our readers have already been made aware, took place on Sunday last, and we may hope, although we shall not know for more than a month, that the weather was favourable. We shall not hear whether the French arrived in time, but we do know that the English observers met the American party, consisting of Prof. Holden, Dr. Hastings, Mr. Rockwell, Mr. Preston,

Lieut. Brown, and Mr. Upton, the first mentioned astronomer being in charge, at Panama. They expected to arrive at Callao on the 20th March last, and to leave either in the *Hartford* or the *Pensacola* within the next few days. That would give them ample time to reach the Caroline Islands, and make the arrangements necessary for the observation. It was the intention of Prof. Holden to take the combined English and American party on to Flint Island if he found that Dr. Jannsen had already established his party on Caroline. This, of course, was a very proper decision, as it would double the chances of favourable weather. We give the time-table for observation supplied to the English observers, which they were instructed to carry out down to its most minute detail, if all the instruments were landed and set up without damage.

It will be seen that the English attack was to be entirely photographic; no eye observations were to be made. And if all has gone well, something between fifty and sixty photographs may be hoped for. The table perhaps requires a little explanation, which we will now proceed to give. It followed from work undertaken with that special object in Egypt last year, that eclipse observations can now definitely begin ten minutes before totality, and end about ten minutes after. With an eclipse therefore of about five minutes' duration, as in the present case, the work ranges over a period of five-and-twenty minutes, and if the plates are as sensitive as they can now very well be, it is quite easy to see that a very large number of photographs may be taken. The greatest interest of course attaches to the spectroscopic photographs to be taken by means of a siderostat and the equatorials. As in former eclipses the plates exposed in the photoheliographs will secure the appearance of the corona surrounding the image of the dark moon; but on the present occasion an attempt was to be made to take these photographs on a much larger scale than usual, a scale of four inches to the moon's diameter. Coming to the spectra themselves, we find

four spectroscopes fed by the light reflected by a siderostat of 30 cent. diameter, these four spectroscopes being bracketed together very much like a Gatling gun, and pointed to the siderostat, which has a very excellent clock attached to it. The first spectroscope, called the "Hilger," in the programme, is an integrating one, and will integrate for us the light of the whole region round the sun during the entire period of totality on a plate which is allowed to fall very slowly by means of a clock-work arrangement. If any change, therefore, takes place in the spectrum of these regions during this period, it will be recorded on this moving plate in historical sequence, so that, the beginning and end of exposure being known, the time at which any definite change takes place can be determined. The Rowland grating coming next on the list, which was generously given to Mr. Norman Lockyer by Professor Rowland, is one of ten feet focus, and has a large surface with 14,000 lines to the inch, forming of course a most excellent and simple prismatic camera, the first and second order spectra both being utilised. The prismatic camera and slit spectroscope of two prisms were two instruments arranged by Capt. Abney for the eclipse last year. They are on the model of the instruments designed for the eclipse of 1875 in Siam, but have the advantage of possessing plates which are sensitive to the whole of the spectrum. The work to be done by the equatorial is of a very similar nature to that to be attempted with the siderostat, except that it was intended by varying the time of exposure from long to very short periods to make certain of something. All the cameras, except the "Hilger," in which the plate moves by clockwork, are fitted with long plates, of which only small strips are exposed at a time, and the exposure is managed, not by changing the plate as in the ordinary method, but by turning a screw. The word "expose" in the table therefore shows the precise moment, at which, if the instructions are carried out, a new strip of plat will be exposed to the action of the light before, during, and after totality, and it will be seen that the exposures are varied both before and after totality, so as to get the greatest possible difference in time during which each part of the plate receives its impression. From a letter received by Mr. Norman Lockyer from Messrs. Lawrance and Woods, we know that the American astronomers intended giving them all possible facilities for carrying out the combined Royal Society and Solar Physics Committee's programme; and that the attention of the English observers will be concentrated on the siderostat and equatorials, as two officers of the American ship have been told off to work the photo-heliographs and look after the eclipse clock, which is so arranged that it keeps all the observers together by indicating to each one of them the exact number of seconds still left for his work, with the additional advantage that each number of seconds announced by the officer in charge is a distinct order to do a certain thing, as in the case of the various exposures indicated in the list.

LECTURES TO WORKING MEN

THE three courses of Lectures to Working Men given at the Museum of Practical Geology, Jermyn Street, during the present session, by the staff of the Normal School of Science and the Royal School of Mines, came to an end last Monday, and, as on former occasions, it gave rise to regret that more cannot be done in this direction, both with regard to the number of courses given, and the number of persons accommodated in each case. The theatre at Jermyn Street restricts the audience to something over 600, while of late years the applications for tickets have never been less than 2,000. The tickets for each course—for which sixpence is charged as a registration fee—are given only to *bonâ fide* working men, who must bring with them a paper on which is stated their name and occupation. Some of the lectures of the last course—that given by Mr. Norman Lockyer, on "The Earth and its Movements"—were listened to by the Japanese Minister, and an official connected with the Education Department of Japan. At their request a list was drawn up showing the trades of the audience. This list, in the case of 500 who attended the last course, we are permitted to give, and we think our readers will find it an interesting one. Seeing that there is this anxiety on the part of working men to learn, and that less than one in three of those so desirous of learning can have an opportunity of doing so, we trust that in future years the Lecture Theatre at South Kensington will be utilised in this direction, as well as that at Jermyn Street. There is little doubt, of course, that a Liberal Government, represented by the Treasury officials, naturally anxious in all ways to protect the public purse against all claims, whether good or bad, might object to this being done at the public cost, but seeing that the lectures are given as a labour of love by the various professors such an objection would scarcely be urged, and we confess too that we should not only like to see the theatre at South Kensington utilised in this way, but the theatres at University College, King's College, and other institutions that might be named. We do not believe that the professors at these institutions are less anxious for the progress of knowledge among the working classes than those who are connected with the Government School, and this being so, we may hope to see at some future time a united effort to supply what is at present a great want, and a gap in our educational programme.

Trades of 500 of the audience at the last course of Lectures to Working Men, April and May, 1883:—

7 Zinc Workers.

CIRRIFORM CLOUDS

IN a "Note on a Proposed Scheme for the Observation of the Upper Clouds" the Rev. W. Clement Ley has written an abstract of part of a large work on clouds, which he is now preparing for publication. This note has been circulated with a view of obtaining suggestions on the scheme of classification, observation, and telegraphy, which the writer has submitted to his colleagues of the Committee on Cirrus observations, nominated by the International Meteorological Committee in 1882.

The author follows the primary outlines of cloud-classification proposed by Luke Howard, dividing the objects of observation into cirriforms, cumuliforms, stratiforms, and composites; while in the subdivision of these primary types he has been induced by reasons, the cogency of which he hopes to demonstrate, to deviate very considerably from Howard's classification. The true cirriforms, to the discussion of which the note is restricted, are divided by Mr. Ley as follows: cirrus, cirro-filum, cirro-velum (with its variety mammatum), cirro-nebula, and cirro-granum. The author has been, "after many years devoted to the consideration of the subject, reluctantly compelled to give up the employment of the two terms 'cirro-stratus' and 'cirro-cumulus.' Their use has led to endless confusion. In point of structure the clouds usually called cirro-cumuli belong essentially to the higher stratiforms, consisting of nubecules separate, or partly coalescing, occupying a layer of atmosphere of very small vertical thickness, but of very great horizontal extent, and they are not formed in nature by those processes which are productive of clouds either of the cirrus or of the cumulus type. They are not, in fact, either in appearance or in mode of physical formation, either compounds of cirrus with cumulus or hybrids between cirrus and cumulus. Therefore in practice the use of the word cirro-cumulus has led to a large number of clouds of no great elevation being classified among the cirriforms, a result which was of little consequence when the laws regulating the upper currents of the atmosphere had received no examination, but which must be absolutely fatal to a scheme based upon those laws, according to which new and most valuable results will be attained. The name cirro-stratus is almost equally objectionable, and for similar reasons."

Six pages of this note are devoted to instructions on a system of observing and reporting by telegraph the structure and movements of the upper clouds; and the author shows that, if this system be adopted on an extensive scale, results of great practical importance may be anticipated. The indispensable pre-requisite is a clear and scientific classification of clouds according to physical structure.

SCIENTIFIC PROGRESS IN CHINA AND JAPAN

VARIOUS steps in the progress of China and Japan in the adoption of Western science and educational methods have from time to time been noticed in these columns. To the popular mind the names of the two countries are synonymous with rigid unreasoning conservatism and with rapid change respectively. The grave, dignified Chinese, who maintains his own dress and habits even when isolated amongst strangers, and whose motto appears to be, *Stare super vias antiquas*, is popularly believed to be animated by a sullen, obstinate hostility towards any introduction from the West, however plain its value may be; while his gayer and more mercurial neighbour, the Japanese, is regarded as the true child of the old age of the West, following assiduously in its parent's footsteps, and pursuing obediently the path marked out by European experience. There is considerable misconception in this, as indeed there is at all times in the English popular mind with regard to strange peoples. Broadly speaking, it is no doubt correct to say that Japan has adopted Western inventions and scientific appliances with avidity; that she has shown a desire for change which is abnormal, and a disposition to destroy her charts and sail away into unsurveyed seas, while China remains pretty much where she always was. She is now, with some exceptions, what she was twenty, two hundred, perhaps two thousand years ago, while a new Japan has been created in fifteen years. All this, we say, is true, but it is not the whole truth. China also has had her changes; not indeed so marked or rapid, not so much in the nature of a *volte-face* on all her past as those of her neighbour. The radical difference between the two countries in this respect we take to be this: that while Japan loves change for the sake of change, China dislikes it, and will only adopt it when it is clearly demonstrated to her that change is absolutely necessary. To the Japanese change appears to be a delightful excitement, to the Chinese a distasteful necessity; to the former whatever is must be wrong, to the latter whatever is is right. As a consequence of this difference between the two peoples, when China once makes a step forward it is generally after much deliberation, and is never retraced. Japan is constantly undertaking new schemes with little care or thought for the morrow, but with the applause of injudicious foreign friends. In a short time she discovers that she has underrated the expense or exaggerated the results, and her projects are straightway abandoned as rapidly and thoughtlessly as they were commenced. Swift suggested as a suitable subject for a philosophical writer a history of human projects which were never carried out; the historian of modern Japan finds these at every turn. Where, for example, are the results of the great surveys, trigonometrical and others, which were commenced in Yezo and the main island about ten years ago? A large, expensive, but highly competent foreign staff was engaged, and worked for a few years; but suddenly the whole survey department was swept away, and the valuable instruments are, or were recently, lying rusting in a warehouse in Tokio. The same story may be told of scores of other scientific or educational undertakings in Japan. An able and careful writer, Col. H. S. Palmer, R.E., who has recently, with a friendly and sympathetic eye, examined the whole field of recent Japanese progress, in the *British Quarterly Review*, is forced to acknowledge this. "Once having recognised," says this officer, "that progress is essential to welfare, and having resolved, first amongst the nations of the East, to throw off past traditions and mould their civilisation after that of Western countries, it was not in the nature of the lively and impulsive Japanese to advance along the path of reform with the calmness and circumspection that might have been possible to a people of less active temperament. Without doubt many foreign institutions were at first adopted rather too hastily, and the passing difficulties which now beset Japan are to some extent the inevitable result." It would be blindness to deny that the net result of the Japanese efforts is progress of a very remarkable kind, but it is a progress which in many respects lacks the firm and abiding characteristics of Chinese movements.

The proverb, *Chi va piano va sano*, which was recommended ten years ago to Japanese attention by an eminent English official, and apparently disregarded by them, has been adopted by their continental neighbours. To the blandishments of pushing diplomatists or acute promoters, the Chinese are deaf. However we may felicitate ourselves on our inventions, scientific appliances, "the railway and the steamship and the thoughts that shake mankind," our progress, the newspapers, the penny post, and what not, China will not adopt them simply because *we* have found their value and are proud of them. But if, within the range of her own experience, she finds the advantage of these things, she will employ them with a

rapidity and decision surpassing those of the Japanese. A conspicuous instance of this will be found in her recent action with respect to telegraphs. For years the Chinese steadily refused to have anything to do with them; the small land line which connected the foreign community of Shanghai with the outer world, was maintained against the violent protests of the local authorities, and the cable companies experienced some difficulty in getting permission to land their cables. But during the winter of 1879-80, when war with Russia was threatening, the value of telegraphs was demonstrated to the Peking Government. The Peiho at Tientsin was closed by ice against steamers, and news could only be carried to the capital by overland couriers from Shanghai. Before a year elapsed a land line of telegraph was being constructed between this port and Tientsin; in a few months the line was in working order, and the Chinese metropolis is now in telegraphic communication with every capital in Europe.

This conservatism, respect for antiquity, conceit, prejudice, call it what we will, has something in it that extorts our respect. Let us imagine a dignified and cultivated Chinese official conversing with a pushing Manchester or Birmingham manufacturer, who descants on the benefits of our modern inventions. He would probably commune with himself in this wise, whatever reply Oriental politeness would dictate to his interviewer: "China has got on very well for some tens of centuries without the curious things of which this foreigner speaks; she has produced in that time statesmen, poets, philosophers, soldiers; her people appear to have had their share of affliction, but not more than those of Europe; why should we now turn around at the bidding of a handful of strangers who know little of us or our country, and make violent changes in our life and habits? A railway in a province will throw thousands of coolies and boatmen out of employment, and bring on them misery and starvation. This foreigner says that railways and telegraphs have been found beneficial in his country; good, let his countrymen have them if they please, but let us rest as we are for the present. Moreover, past events have not given us such faith in Europeans that we should take all they say for wisdom and justice." A day will undoubtedly come when China also will have her great mechanical and scientific enterprises; but what we contend for here is that nothing we can say or do will bring that time an hour nearer. European public opinion is to China a dead letter; she refuses to plead before that tribunal. Each step of her advance along our path must be the result of her own reflection and experience; and our wisest policy would be to leave her to herself to advance on it as she deems best.

SINENSIS

PROF. LINDSTRÖM ON OPERCULATE CORALS[1]

THE extinct stony corals, the calicles of which are provided with calcareous opercula, have ever been a puzzle to naturalists, since they are almost entirely without parallel amongst existing Anthozoa. The genera and species are not numerous, and are all of Palæozoic age. By far the finest and best preserved specimens of the most important forms are found in the Silurian strata in the Island of Gothland in the Baltic, and are collected for the National Museum at Stockholm, where they come under the care of Prof. Lindström, the author of the present memoir, so justly distinguished for his palæontological researches generally, and especially for those on corals. In this memoir he gives a *résumé* of all the forms of operculate corals as yet known, embodying an immense amount of important new information derived from his own prolonged investigations on a series of most remarkable specimens which I had the advantage of seeing and having explained to me by him in the summer of last year. The whole paper forms a most valuable contribution to our knowledge of these especially interesting and peculiar corals.

FIG. 1.—*Goniophyllum pyramidale* (*mutatio secunda*), viewed from above, with the opercular valves *in situ* of the natural size.

The first operculate coral described was *Goniophyllum pyramidale*, which Bromell in 1729 placed amongst the corals. The best known, and the one concerning which there has been the greatest difference of opinion, is *Calceola sandalina*, which was first figured in 1749 from the collection of Rosinus of Hamburg, by Brüchmann, who pointed out the resemblance of the coral to the front of a woman's slipper.

Brüchmann referred Calceola to the corals just as Bromell had Goniophyllum, but this was mainly because neither he or other early authors following him were acquainted with the opercula belonging to the specimens. Linné placed Calceola with the Mollusca as *Anomia sandalina*. Later it was referred to the Brachiopoda, a position in which a large number of eminent modern authorities retain it. If Calceola stood alone, the gravest doubts might certainly be entertained as to its having any relations to the corals; but now that a series of clearly allied forms such as Goniophyllum and Rhizophyllum, also bearing opercula, have had their structure so fully and satisfactorily worked out as has been done by Prof. Lindström, it is hardly possible not to follow him in placing the whole amongst the Anthozoa. The curious arrangement of the septa in Calceola closely resembles that in Goniophyllum as regards the septa both in the calicles and on the opercula. It is almost impossible to doubt the Anthozoan nature of Goniophyllum, whilst both it and Rhizophyllum, which has like Calceola an operculum of a single piece only, demonstrate their close relation to numerous recognised Palæozoic corals by exhibiting intracalicynal gemmation, and developing, like many other corals, abundance of roots.

The author divides the *Anthozoa operculata* into two families—

I. Calceolidæ (or Heterotœchidæ), distinguished by having the septa on the inner face of the operculum not alike and a median septum the largest.

II. Aræopomatidæ (or Homotœchidæ), with the septa on the operculum all alike and no defined median septum.

The Calceolidæ include all those forms in which the operculum, whether composed of one or four valves, has this valve or valves marked inside with a stout prominent median septum.

The family falls into two groups—the one in which the operculum consists of a single valve containing three genera, namely, the well-known Calceola, distinguished by not multiplying by budding, being thus never compound, by having no root-tubes, and not showing vesicular structure internally; and two others—Rhizophyllum and Platyphyllum—in both of which calicynal gemmation occurs and the internal structure is vesicular, somewhat as in Cystiphyllum.

In Rhizophyllum, a genus founded by Lindström, the

[1] "Om de Palæozoiska Formationernas Operkelbärande Koraller." Af G. Lindström, Bihang till K. Svenska, Vet. Akad. Handlingar, B. 7, No. 4.

corallum is very much like that of Calceola in shape, but more elongated. It may be simple or form large masses by two modes of budding—either calicynal budding, or budding from the abundant rootlets. In the specimen of

FIG. 2.—*Rhizophyllum elongatum.* View of the interior of the calicle to show the six young calicles developing as buds within it.

Rhizophyllum here figured, six young corals are seen in the act of developing as buds in the interior of the calicle.

In consequence of budding taking place from the "rootlets," the author advances the new suggestion that these bodies, the nature of which has always been doubtful, are to be regarded as stolons. The operculum of Rhizophyllum, by which the mouth of the calicle is completely closed, is, as in Calceola, of a semicircular shape, with a prominent ridge-like median septum on its inner face. In *Rhizophyllum attenuatum*, a compound form from Louisville, in Kentucky, first described by Mr. V. W. Lyon under the genus Calceola, the stolon tubes partly serve to connect together adjacent calicles, partly become themselves developed into fully-formed calicles. Specimens of *Rhizophyllum Gothlandicum* are found in abundance in the Island of Gothland with their opercula detached. The separate opercula are also common; specimens with the opercula *in situ* are comparatively rare. A remarkably perfect one is shown in the accompanying figure.

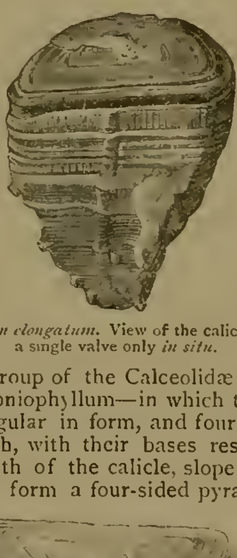

FIG. 3.—*Rhizophyllum elongatum.* View of the calicle with the operculum, a single valve only *in situ*.

The second group of the Calceolidæ contains only a single genus—Goniophyllum—in which the mouth of the calicle is rectangular in form, and four opercular valves are present which, with their bases resting on the four sides of the mouth of the calicle, slope inwards to meet one another, and form a four-sided pyramidal roof over

FIG. 4.—*Goniophyllum pyramidale* (*mutatio prima*). View of the mouth of the calicle, with the opercular valves *in situ*, the dorsal right and left valves being entire, the ventral incomplete.

the calicle. From Gothland Prof. Lindström has been able to obtain two or three specimens with all the four opercular valves *in situ*. So that doubts as to the connection of the valves with the coral calicle are now inadmissible. On careful study of these specimens and numerous others with a fewer number of valves *in situ*, he finds that the four valves always present well-marked differences and form, and septal striation, so that it is possible to distinguish with certainty an anterior and posterior, or ventral and dorsal, and a right and left valve, and pick these out from any collection of well-preserved loose valves. The anterior and posterior valves are trapezoid in form, the lateral triangular. A most remarkable discovery he has made is that these corals must have shed their valves periodically, and replaced them, and that when shed the valves frequently happened to become attached to the wall of the calicle, and fused with it. In the accompanying figure of *Goniophyllum pyramidale*, seen from behind, a well-formed operculum is seen near the base firmly attached to the wall of the calicle near its base. Such

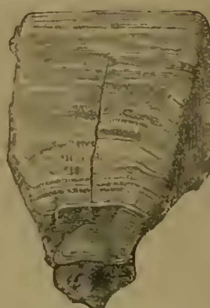

FIG. 5.—*Goniophyllum pyramidale*, viewed from the ventral side to show the shed opercular valve (*a*) coalesced with the wall of the calicle near its base.

specimens are not uncommon in Goniophyllum, but in another genus, a new one, Aræopoma, belonging to the second family of operculate coral, devoid of a median septum, and which has four triangular valves like Goniophyllum, very many specimens bear numerous valves fused to their outer walls, the valves being of increasing size from below upwards, in accordance with the growth and expansion of the coral and the mouth of its calicle. In one abnormal specimen of *Goniophyllum pyramidale* there are five opercular valves present, a minute extra triangular valve being interpolated at one of the corners.

Prof. Lindström, whose important researches on the development of the septa in so-called Rugose corals are familiar, has been able to trace the development of the corallum in *Goniophyllum pyramidale*. He finds that in the youngest stage of the calicle there is no septum present at all, then that one septum is formed on what may be termed the dorsal side of the calicle, and since in this genus and several others it remains conspicuously prominent, it may be termed the primary septum. Two further septa, the light and left median, are next formed, and last of all the ventral septum, long after the others. He points out that a similar process of development is followed in most Rugose corals, and that it is therefore erroneous to treat of four septa as primary in these forms.

In Rhytidophyllum shaped somewhat like Calceola, but belonging to the Aræopomatidæ, by reason of the absence of a defined median septum on the operculum there is only a single opercular valve. A further genus of the group is possibly represented by a single broken operculum, of which further specimens have not yet been found.

In connection with the operculate corals, Prof. Lindström describes certain coral forms in which remarkable exothecal structures are present, which may be considered as more or less homologous with opercular valves. In *Pholidophyllum tubulatum*, a compound coral, first described as *Tubiporites tubulatus* by Schlotheim in 1813,

and which has lately been made a subject of research by G. von Koch, the costæ are in solitary specimens clad each with a longitudinal rib composed of a double row of rhomboidal calcareous scales placed close together at an angle to one another as shown in the figure. These rows of scales form an almost complete outer covering to the corallum. The scales seem to be wanting in colonial specimens. They are extremely conspicuous and definite in some of the best preserved solitary specimens, and their regularity of disposition is such that it is impossible to believe that they do not definitely belong to the coral. They are shown enlarged in the figure. In vertical sec-

FIG. 6.—*Pholidophyllum tubulatum.* A calicle viewed from the side to show the rib-like prominences formed upon the costæ by the double rows of calcareous scales.

tions of the coral they are seen to be attached at their bases to the wall of the calicle. In *Syringophyllum organum* similar scales occur covering the exterior of the corallum, but these have a remarkable definite form somewhat like that of the bowl of a teaspoon with the handle cut off short.

As an illustration of the possibility of Anthozoa bearing opercula and scales, but not as implying any direct relationship between the Operculata and the Alcyonaria, Prof. Lindström points to the structure of *Primnoa lepadifera*, and figures one of the polyps viewed from above, showing how eight of the valve-like calcareous scales present in this species close in over the summit of the polyp, forming a conical operculum over it somewhat as in Goniophyllum, whilst the remaining scales form a representative of the calicle. He shows that, as in Goniophyllum, the opercular valves differ in form and size according to their position when *in situ*.

In his concluding paragraph he states that he considers the Calceolidæ to be probably nearly allied to such forms as Omphyma and Chonophyllum, whilst the Aræopomatidæ, on account of their vesicular internal structure, approach more nearly to Cystiphyllum. He does not consider the presence or absence of an operculum in corals to be necessarily of an important classificatory value, and cites the case of the presence and absence of opercula in Gastropoda as a parallel one of minor systematic importance. In this it is rather difficult to agree with him. Of course the opercula in Gastropods and corals are alike only in name, and as they occur so rarely in the latter the suspicion naturally arises that the two groups of the operculate corals may be more closely allied than he suspects. However, no man knows them better than he, or has a better right to an opinion on the subject, and his conclusion, guarded as it is, must be treated with all respect.

A very interesting result attained and given in tabular form on p. 91 is that in successive Upper Silurian strata a series of three modifications of form of *Goniophyllum pyramidale*, starting from *Goniophyllum pyramidale, primigena,* the form occurring in the lowest beds can be traced succeeding one another in time. Similarly *Rhizophyllum Gothlandicum, forma primaria* passes by a modification, *R. G. mutalia*, into *R. Gervillei*, of specific rank in the Devonian formations. Other operculate corals show similar modifications in progress of geological time. Prof. Lindström's important memoir cannot here be followed farther. It is illustrated by nine lithographic plates most beautifully executed in Stockholm, from which the engravings here given are copied, and are some of the most excellent ever published of corals.

H. N. MOSELEY

BARON NORDENSKJÖLD'S EXPEDITION TO GREENLAND

[THE following Programme, drawn up by Baron Nordenskjöld for his expedition to Greenland, has been kindly placed at our disposal by Mr. Oscar Dickson, who, with his well-known enlightened liberality, provides all the expenses. The Programme has not hitherto been made public, even in Sweden, as Baron Nordenskjöld did not wish to be interrupted in his preparations with correspondence on his plans and theories. The expedition leaves Sweden in the *Sofia* on the 20th instant, and will call at Thurso, where Baron Nordenskjöld will join the vessel.]

NINE centuries have elapsed since the Norwegian, Erik Röde, discovered Greenland, and founded Scandinavian Colonies; from these, Norwegian navigators some ten years after sailed south to "Vinland," the fecundus, *i.e.* to the shores of the present Canada and the United States, thereby acquiring the honour for the Norse race of being the real discoverers of the New World. It is not known whether these voyages led to any fixed settlements being established in America, but we know, on the other hand, from a number of Icelandic sources, that the colonies in Greenland became very flourishing. There were upwards of three hundred farms, "Gaarde," of which about two hundred, embracing twelve parishes, were situated in the "Österbygd," and about one hundred, embracing three or four parishes, were situated in the "Vesterbygd." During four centuries the country formed a bishopric, from which funds towards the Holy Wars were even contributed. Unfortunately, the connection between the colonies and the mother country ceased after a couple of centuries, while Greenland's ancient Norse population was extirpated, either through plagues or by "Skrællings," *i.e.*, the Eskimo who descended from the North. Another explanation of their disappearance is that they lost their nationality, and were absorbed into the Eskimo population, during their contact with the more numerous tribes of the Polar regions, whose mode of living was more suited to the climate of the country and the resources at their disposal. However that may be, there remains the fact that one of the most distinct and enterprising peoples in the world have been annihilated, or, perhaps, absorbed in one distinguished as among the lowest, both physically and intellectually. The old country, belonging to the Norwegian Crown, was even so far forgotten, that it was only Columbus's discovery in the south which recalled the attention of the Norsemen to the fact that they had once colonised a part of this world, which was being parcelled out among the southern nations by "Bulls" from Rome, as if it had just been discovered.

By the aid of traditions and old journals of navigation several attempts were made to reach the old, forgotten colonies from Iceland, but these were frustrated by the enormous masses of drift ice, which then seemed to inclose the shores of Greenland's east coast, more than formerly. Eventually, John Davis, in his attempts to find the north-west passage, discovered that the west coast was easily reached, and that the seas around it offered a fine hunting-ground for the profitable whale-fisheries. This, with the reported discovery of gold in the country resulted in the despatch of several Danish hunting and commercial expeditions, which did not, however, meet with much success, until the Norwegian

Hans Egede, by his zeal for bringing the blessings of the Gospel to the descendants of the old Norse colonists, caused trading and missionary stations to be established on the west coast. These were subsequently considerably augmented and extended, and henceforth held by the Danish crown, under "The Commercial Association of Greenland."

Greenland was thus inhabited by Norsemen from 983 until the 15th century, and its west coast has, during the last hundred and sixty years, been a place of sojourn for many able Danish administrators and missionaries. Besides this, nearly all expeditions which have been bound for the American Polar sea have stayed here more or less, while the west coast has on many occasions been the object of carefully prepared expeditions of research. This part of Greenland is, therefore, scientifically and ethnographically one of the best-known of the Arctic lands. But in spite of this we encounter here several of those *lacunæ* in the knowledge of the globe which it is of great importance that we should fill up, and some of these it is now my intention to deal with.

The east coast of Greenland was visited in 1822 by the Englishman, Scoresby, jun., and in 1823 by Sabine and Clavering, in 1829-30 by the Dane, W A. Graah, as well as by the second German expedition under Koldewey in 1868-69, and also by some whalers. It is, however, in its greatest extent wholly unknown, a circumstance, which must be detrimental to the proper understanding of the history of the first Norse colonisation of Greenland, and of early voyages of conquest and discovery therefrom to the shores of America. Thus, until the east coast of Greenland is fully explored, one must continue to doubt the very forced explanation of the site of these colonies which is now predominant in the world of science. And it is, on the other hand, not worthy of the geographical discoveries of the 19th century, that a coast-line extending south to the latitude of Stockholm should be so utterly a *terra incognita.*

The interior of Greenland is even less known than the east coast, and here we encounter a purely scientific problem, whose great importance is apparent from the circumstance that the unestablished theory,—that the interior of the island is one continuous mass of ice,—forms one of the corner stones in glacial science, which again is closely connected with several of the fundamental principles of modern geology. If we except a trip on the inland ice of Greenland in 1751, in lat. 62° 31′ by the Danish merchant Lars Dalager, who penetrated nearly thirteen kilometres across a comparatively even plateau, and the unsuccessful attempt by Whymper in 1867, in lat. 69° 30′, where no progress was possible, in consequence of the difficult nature of the ground, only two serious attempts have been made to explore the interior of Greenland. The first of these was made by Dr. Berggren and myself between July 19 and 26, 1870, in lat. 68° 30′. Favoured by the most magnificent weather, we were able to penetrate nearly fifty kilometres across a country at the outset very difficult and rent by bottomless abysses, but which gradually improved in condition the further we advanced. We had on starting the company of two Eskimo, but they left us after two days' journey. As those who claimed to know the coast glaciers of Greenland had advised me not to waste time and labour on such a hopeless undertaking as that of penetrating over the inland ice, my outfit was very incomplete; we were in want of ropes, tent, suitable sledges, and on the Eskimo leaving us we could not even carry the utensils necessary for cooking. I could not therefore on that occasion get very far, but I certainly came to the conclusion, that I should have been able, with a couple of smart sailors or Arctic hunters and a suitable outfit, easily to have extended my wanderings to 200 or perhaps 300 kilometres. I may also mention here that in the month of June, 1873, I effected with Capt. Palander and nine sailors a journey of more than 190 kilometres over the inland ice of Spitzbergen, which journey was of special interest to me from the circumstance that I here learnt to know the character of inland ice before thaw sets in, as well as the difficulties which are at such a time attendant on journeys on the glaciers of the Polar regions. This experience, I believe, will be of great use to me during the journey now in course of preparation, as I shall have to cross portions of the inland ice which, on account of the altitude, will still be covered with snow at the time of my visit.

The second journey of research on the inland ice of Greenland was made between July 14 and August 4, 1878, in lat. 62° 40′, by the Danes, J. D. Jensen and A. Kornerup. This expedition was carefully equipped, but the country being much fissured, and the weather unfavourable, it did not reach much further inland than the Swedish of 1870.

None of these expeditions saw any limit to the ice desert from their farthest point, but to infer from this that ice covers the whole interior of Greenland appears to me to be entirely unjustifiable. On the contrary, the following reflections seem to demonstrate that it is a *physical impossibility* that the whole of the interior of this extensive continent can be covered with ice, under the climatic conditions which exists on the globe south of the 80th degree of latitude.

The ice masses of the glaciers are commonly termed "permanent," a denomination which was once taken so literally that certain *savants* asserted that the ice in course of time was transformed into mineral crystals, such as those which are so frequently found in the clefts of the Alps. We know now that this term is entirely erroneous. The glacier which seems century after century to fill the same valley is not only in constant, although imperceptible, motion, by the ice masses which slowly advance from higher to lower elevations, but is also subjected to a change in its form by the circumstance that the lower stratum melts away through contact with the mountain on which it rests; while the surface on one side wastes away by thawing in the warm season and evaporation in the cold, and on the other is added to by falling snow, which latter after a time changes from snow dust to granular snow, then to crystals of ice, and eventually to a compact homogeneous mass of ice. And, if the advancing glacier is "fed" by enormous ice-fields, or what I may term "ice-lakes," situated so high that snow always falls there copiously, it can penetrate far below the border of the perpetual snow, yea, even to parts where the snow-fall is far from sufficient to make up for the loss of melting and evaporation. It is therefore clear, that glaciers, or other constant ice-masses, cannot form in places where they cannot be "fed" by descending ice, or where the snow-fall is less than the quantity which appears and disappears yearly; a circumstance which, among others, explains why no glaciers exist in the vicinity of the north polar coasts of the new or old world.

With regard to Greenland it is not difficult to demonstrate that the above-described conditions for the formation of glaciers do not exist there, if the country does not rise gradually both from the eastern and the western shore to the centre, and thus be like a loaf of bread in shape, and with sides slowly and symetrically terminating in the ocean. Such a land-formation is, however, not found in any part of the orography of the known world, and one may therefore safely conclude that neither is it to be found in Greenland. In fact, the geological nature of Greenland, very similar to that of Scandinavia, seems to indicate a similar orographical formation, viz., a formation formed of mountainous ridges alternating with deep valleys and plains; while one may even assume that the culminating line of the land in Greenland runs, as in England and Sweden, and in both American continents, along the west coast.

The winds, therefore, which should produce snow in the interior, must, if coming from the Atlantic, have in the first instance, crossed the broad ice-belt generally encircling the east coast of Greenland, and then the mountains on the coast, some of which we know are very high, and, if coming from Davis Sound, the mountain ridge itself. In both cases the wind would assume the character of the "Föhn" wind, *i.e.*, it must, after passing the mountain-chains on the coasts, be *dry and comparatively warm*. The law of the "Föhn" is, as is generally known, dependent on the circumstances explained below.

If ACB indicates a mountain, and a wind so dry that no deposit of moisture takes place on the top passes from AC to B, the air will certainly be chilled in passing C, in consequence of the lower barometric pressure and consequent expansion of the air; but the same cause which produces the lowering of temperature when the wind ascends has also the effect of liberating its heat, and the air will become warmer as it descends from C to B. The compression and rise of temperature are in the latter case precisely analogous to the expansion and fall of temperature in the former, and the dry air, in passing

the mountain, has, therefore, on reaching B, not suffered any change whatever in temperature or quantity of moisture. Quite different will, however, be the result if the air ascending at A is saturated with moisture, as, for instance, air passing a great expanse of water. In that case the air will expand and become colder, just as it ascends from the water surface to the mountain top, but, at the same time, part of the moisture will be condensed on the top, whereby the latent heat of the hydrogen will be set free and a rise of temperature take place, and this will, to a certain extent, minimise the fall of temperature caused by the expansion of the air. The air will retain the heat thus set free, even after it has reached, in a dry state, the point B, and the air, originally moist, has, when it has passed the mountain, attained a higher degree of heat, but less moisture than at the moment of ascending. *It is in fact dry and warm.*

These causes are not only the reason of the dry warm "Föhn" winds in Switzerland, and the very remarkable circumstance that it is under winds from the snow-covered mountains that the snow disappears in Swedish Lappland, but they play also an important part in the climatic conditions of the whole globe. They are, for example, the cause of the difference in climate and flora of the two sides of the Andes, of the east and west coasts of Tierra del Fuega, and the eastern and western parts of Australia. They are the chief cause of the deserts which cover the interiors of Asia, Australia, the northern portion of Africa, and certain parts of America, while in Sweden they produce the constant western winds, and the consequent prolonged drought which invariably occurs in spring time in the central part of the country. The same laws of the temperature and moisture of the air must also prevail in Greenland. Here too the ocean winds must be moist, and this moisture is usually deposited in the form of snow on the mountains along the coast, whereas all those reaching the interior, whether from east, west, north, or south, must—if the orographical construction of the country is not entirely different from that of others on the globe—be dry and comparatively warm. And in consequence of this circumstance, the snow-falls in the interior of Greenland cannot be sufficient for maintaining a "perpetual" inland ice.

It cannot, however, be asserted that the country should here form a deserted, treeless tundra; one encounters in Siberia forests with giant trees under climatic conditions far more severe than those we may assume are to be found in the interior of Greenland. That the country should prove true to its name has besides been asserted by the celebrated botanist Hooker, from his studies of the flora of Greenland, and even the natives on the west coast themselves have a suspicion that such is the case, from the large herds of reindeer which from time to time are seen to migrate across the inland ice to the west coast.

It is most probable that the interior, if free from ice, is like a North European high plateau, with a flora far more copious than that of the coast.

But this I maintain, that whether the interior of Greenland is richly covered with forests, as the land round the frigid pole of Siberia, or is a treeless, ice-free tundra, or even a desert of perpetual ice, the solution of the problem of its real nature is so important, and of such consequence to science, that there could hardly, at the present moment, be conceived an object more worthy of an Arctic expedition than to ascertain the true conditions of the interior of this particular country.

Besides the object of penetrating to the interior of Greenland, the expedition will have several others in view, of which I may mention the principal:—

To Fix the Limit of the Drift-ice between Iceland and Cape Farewell, and to take Soundings and Dredgings in the Adjacent Seas

This part of the Atlantic has hardly ever been subjected to any other kind of examination than that made on laying the first cables. A knowledge of the same is, however, of great importance, both for completing the missing link in the hydrographic chain of the Ocean dividing Europe and America, and for the discovery of the causes of the change in the ice-conditions in the seas of the east coast which seem to have taken place since Greenland was first discovered. Without much waste of time the expedition may be occupied with these researches during the voyage from Iceland to the Greenland promontory, which will take place in a season when fine weather may be presumed to reign here, while they may, although with less probability of being favoured by this condition, be effected during the return journey.

The Collection of Fresh Specimens of the Flora of the Ice and Snow

Professor Wittrock is at present engaged in publishing a very interesting and important work on the microscopic flora, with several varieties, whose home is in the snow and ice-fields of the Alps and the Polar regions, for which materials have been brought home from the latter by the Swedish Arctic expeditions. My expedition will, during the coming visit to Greenland, be in a position to gather further materials for researches, which have already revealed to us the startling fact, that even snow and ice can form the bed for a flora regular in development, and of many varieties.

New Systematic Researches of the Strata which in Greenland contain Fossil Plants

From the previous Swedish Arctic expeditions, and through the publications in the *Journal* of the Swedish Academy of Sciences of articles by Prof. Oswald Heer, of Zurich, we know that students of science have received during the last twenty years from the sandstones and slates of North Europe an additional abundant material for determining the pre-historic climatic conditions of the earth ; as well as a knowledge of the certainly variable, but even in the last geological era copious, flora which during these ages existed in the present ice-covered regions of the pole. It is well known, that valuable materials for the study of this phenomenon has been collected in Greenland by English, Danish, and Swedish explorers ; but hitherto what has been brought home has been gathered under very difficult conditions, and generally by men who have not been students of the science in question, viz., palæontology. I hope to attach to my coming expedition one of the most celebrated students of this science, and if this be the case, the expedition will undoubtedly bring home novel and circumstantial details relating to this important chapter of the history of the earth. This task is so much easier to accomplish as the richest fields for the discovery of such fossil objects are situated just where it is my intention to invade the inland ice. During the period I shall be absent wandering on the ice, the other members will be occupied in this pursuit.

The Collection of New Data Connected with the Fall of Cosmic Dust

It is clearly demonstrated by the discovery of cobalt containing iron particles in fresh snow in Europe, and the carbon-dust, also containing cobalt-iron, which is found on the ice-fields north of Spitzbergen, as well as by the appearance of metallic iron in "krykonit," a remarkable dust which I brought home from the Greenland ice, that the fall of a small quantity of cosmic dust always takes place, regularly or periodically, most probably in every part of the globe. But that there is a greater variation in the nature of this fall than is generally assumed, is clearly indicated by the discoveries which were made in the *Vega* expedition, viz., of tiny yellow crystals in the snow on an ice-plateau near the Taimur peninsula. This certainly necessitates fresh researches into this phenomenon, in order to settle questions of great moment to geology and cosmology. It is very difficult to investigate this feature of cosmology, in consequence of the small quantities of dust which falls, and when it takes place in closely populated districts, covered by dwellings and factories, and where the ground is perhaps only clad in snow during a short period of the season. The Polar countries, on the other hand, are particularly suited for researches of this kind, both in consequence of the purity of the air and the absence of terrestrial dust, and by the ease with which the dark dust-particles are noticed on pure snow. The coming expedition will, while steaming along the ice-belts between Iceland and Greenland, and during my wanderings on the ice, be able to direct a great deal of attention to these captivating problems.

Should the conditions of the ice in Baffin's Bay be favourable, and the vessel, when in the vicinity of Disco Island, have sufficient coals for a journey northwards, or should it be possible to obtain a sufficient supply from the beds found in these parts, it would be highly desirable that the members remaining on board whilst I am away on the inland ice make an excursion along the west coast as far as Cape York.

There are, according to statements made to the Arctic explorers Ross and Sabine, lying here on a mountain, Savilik, *i.e.*, the iron mountain, lat. 76° 10′, a couple of large, round, solitary iron blocks, from which the natives obtain the little supply of iron which they require for hunting implements and domestic utensils. The metallic constituents of these blocks are, according to an analysis made of one of these utensils brought home, iron and a small percentage of nickel, and, to judge from the descriptions by the Eskimo, these blocks are of the same nature as those which I discovered in 1870 at Ovifak, on Disco Island. It is very strange that the remarkable descriptions by Ross and Sabine should not have been the object of investigation by the many Arctic explorers who have passed this spot. An opportunity is now at hand to ascertain the much-disputed nature and origin of these iron blocks, while a few days' sojourn on this part of the coast, which is so little known, ought to be of considerable scientific value, especially as the geological features here are similar to those on Disco Island,—strata bearing fossil plants.

This expedition will, as has been the case with previous Swedish Arctic expeditions, be accompanied by a specially selected scientific staff, whose members will individually contribute to make the expedition worthy of earlier achievements, and who will lose no opportunity of adding to our knowledge of the Polar regions. They will attempt to solve some of the many problems which await investigation in the far north. It is, however, impossible to detail at length the researches which may be undertaken, as these must depend on the nature of the special studies to which the members have devoted their time.

There is, however, one more object of research to be mentioned, which should not be lost sight of by any expeditions to Greenland, viz., to attempt to solve the question : Where were the former Norse colonies, Eriksfjord, Brattelid, Garda Cathedral, Herjolfsnæs, and others situated ? This question has already been answered by the most eminent students of the early history of Greenland, who maintain that the ancient Österbygd lies west of the southern part of the island, between Cape Farewell and lat. 61°, and the Vesterbygd, a little north of the west coast. But it appears to me that, if the Icelandic Sagas are examined carefully, and without any preconceived opinion, it will become apparent that former investigators of this problem have been led astray, and that the true Eriksfjord, with its cathedral and numerous parishes, has never been found, but must be sought for on the inaccessible east coast north of Cape Farewell.

With the experience I have of the conditions of the ice in other parts of the Polar seas, I believe that this coast may be reached, without much difficulty, by sailing in the autumn from the south in the ice-free channel, which I have every reason to believe forms along this coast. This journey will, however, not be begun until the commencement of September, and this circumstance will exactly fall in with the plan in view, viz., on returning from the inland ice to attempt this voyage of discovery.

With the premises I have here detailed before me, I now have to suggest the following plan for the journey of the expedition :—

The expedition should leave Sweden near the end of May in a suitable, but not too large, steamer built of Swedish iron and constructed with water-tight compartments. And although the journey is intended for the summer months only, it should be provisioned for one year, and be provided with the necessary winter outfit, with the scientific instruments desirable, and accoutrements which would be of service for the journey on the inland ice. The steamer should be navigated by a man accustomed to sailing in the Arctic seas, whilst there ought also to be on board as ice-master a skipper who has hunted in the Arctic. The scientific staff should, besides the commander, consist of four persons, the doctor included.

From Sweden the steamer should steam to a port in Scotland, where more coals are to be taken on board, and the journey continued to Reikiavik in Iceland. There a

stay will be made for a few days, when the edge of the ice in the west will be made for, which will be followed southwards, but no attempt should then be made to penetrate the pack. Only in case there should be found an open lead, which is not expected, this will be entered. The probability of this is, however, very small. After having passed Cape Farewell, the vessel will call at Ivigtuk, where again it will be coaled from the depots which have been laid up here for the use of the steamer. The course will then be shaped for the west coast of Greenland, probably calling at Egedesminde, to the Auleitsivik Fjord, from the bottom of which the ice-journey will be commenced.

This latter will occupy, it is estimated, thirty to forty days, and should be finished thus by the middle of August next. During this time the vessel will steam through the Waigatt to Omenak, where the many deposits of fossil plants will be visited. If the ice and coals should permit, the vessel will steam northwards, if possible as far as Cape York, whereby an excellent opportunity will be offered for geological, mineralogical, botanical, and zoological studies. In the middle of August the vessel will again be due in the Auleitsivik Fjord, and taking the members of the ice-expedition on board, will steam south to Ivigtuk, where a few days' stay will be made for coaling, etc. From here the vessel will steam round Cape Farewell, along the east coast in the open channel, which I expect to find there at that season; and my intention is then, with due reference to the old geographical descriptions of the Icelandic Sagas, carefully to search the fjords which may be accessible.

At the end of September the return journey will be commenced outside the belt of pack-ice to Reikiavik and home.

The distances the vessel will cover are, in round figures, these:—

			Nautical Miles.
GOTHENBURG ...	to	THURSO	500
THURSO	„	REIKIAVIK	700
REIKIAVIK	„	IVIGTUK	870
IVIGTUK	„	AULEITSIVIK FJORD	540
AULEITSIVIK FJORD	„	OMENAK	330
OMENAK	„	CAPE YORK	400

A. E. NORDENSKIÖLD

NOTES

THE Fifty-third Annual Meeting of the British Association will commence on Wednesday, September 19, 1883, at Southport. The President Elect is Arthur Cayley, LL.D., F.R.S., Sadlerian Professor of Mathematics in the University of Cambridge. The Vice-Presidents Elect are the Right Hon. the Earl of Derby, the Right Hon. the Earl of Crawford and Balcarres, the Right Hon. the Earl of Lathom, Prof. J. G. Greenwood, LL.D., Prof. H. E. Roscoe, LL.D., F.R.S. The General Treasurer is Prof. A. W. Williamson, Ph.D., F.R.S., University College, London. The General Secretaries are Capt. Douglas Galton, C.B., F.R.S., and A. G. Vernon Harcourt, F.R.S. The Secretary is Prof. T. G. Bonney, F.R.S. The Local Secretaries are J. H. Ellis, Dr. Vernon, T. W. Willis; and the Local Treasurer the Mayor of Southport. The Sections are the following:—A.—Mathematical and Physical Science.—President: Prof. Henrici, F.R.S. Vice-Presidents: Prof. Balfour Stewart, M.A., LL.D., F.R.S., F.R.A.S.; Prof. Stokes, M.A., D.C.L., LL.D., Sec.R.S. Secretaries: W. M. Hicks, M.A.; Prof. O. J. Lodge, D.Sc.; D. McAlister, M.A., M.B., D.Sc. (Recorder); Prof. Rowe, M.A., B.Sc. B.—Chemical Science.—President: J. H. Gladstone, Ph.D., F.R.S. Vice-Presidents: Hugo Müller, Ph.D., F.R.S., For. Sec. C.S.; Prof. T. E. Thorpe, Ph.D., F.R.S., F.C.S. Secretaries: Prof. P. Phillips Bedson, D.Sc., F.C.S. (Recorder); H. B. Dixon, M.A., F.C.S.; H. Foster Morley, M.A., B.Sc., F.C.S. C.—Geology.—President: Prof. W. C. Williamson, F.R.S. Vice-Presidents: Prof. W. Boyd Dawkins, M.A., F.R.S., F.S.A., F.G.S.; J. W. Hulke, F.R.S., Pres.G.S. Secretaries: R. Betley, F.G.S.; C. E. de Rance, F.G.S.; W. Topley, F.G.S. (Recorder); W. Whitaker, B.A., F.G.S. D.—Biology.—President: Prof. E. Ray Lankester, F.R.S. Vice-Presidents: Prof. Gamgee, M.D., F.R.S.; W. Pengelly, F.R.S., F.G.S.; Prof. Schäfer, F.R.S.; W. T. Thiselton Dyer, M.A., B.Sc., F.R.S., F.L.S. Secretaries: G. J. Haslam, M.D.; W. Heape; Prof. A. M. Marshall, M.A., M.D., D.Sc.; Howard Saunders, F.L.S., F.Z.S. (Recorder); G. A. Woods. Department of Anthropology: W. Pengelly, F.R.S., F.G.S. (Vice-President), will preside. Secretaries: G. W. Bloxam, M.A., F.L.S. (Recorder); Walter Hurst. E.—Geography.—President: Lieut.-Col. H. H. Godwin-Austen, F.R.S., F.G.S., F.R.G.S. Vice-Presidents: Sir Rawson W. Rawson, K.C.M.G., C.B., F.R.G.S.; The Rev. Canon Tristram, M.A., LL.D., F.R.S., F.L.S. Secretaries: John Coles, F.R.A.S., F.R.G.S.; E. G. Ravenstein, F.R.G.S.; E. C. Rye, F.Z.S. (Recorder). F.—Economic Science and Statistics.—President: R. H. Inglis Palgrave, F.R.S., F.S.S. Vice-Presidents: Prof. R. Adamson, M.A., LL.D.,; J. Heywood, F.R.S., F.G.S., F.S.A., F.S.S. Secretaries: Prof. H. S. Foxwell, M.A., F.S.S.; J. N. Keynes, M.A., B.Sc.; Constantine Molloy (Recorder). G.—Mechanical Science.—President: James Brunlees, F.R.S.E., F.G.S., Pres. I.C.E. Vice-Presidents: W. H. Barlow, F.R.S., M.I.C.E.; Prof. Osborne Reynolds, M.A., F.R.S. Secretaries: A. T. Atchison, M.A., C.E.; Edward Rigg, M.A.; H. T. Wood, B.A. (Recorder). The first general meeting will be held on Wednesday, September 19, at 8 p.m., when Sir C. W. Siemens, D.C.L., LL.D., F.R.S., F.C.S., M.I.C.E., will resign the Chair, and Prof. Cayley, M.A., LL.D., F.R.S., V.P.R.A.S., President Elect, will assume the Presidency, and deliver an address. On Thursday evening, September 20, at 8 p.m., there will be a soirée; on Friday evening, September 21, at 8.30 p.m., a Discourse on Recent Researches on the Distance of the Sun, by Prof. R. S. Ball, LL.D., F.R.S., Astronomer Royal for Ireland; on Monday evening, September 24, at 8.30 p.m., a Discourse on Galvani and Animal Electricity, by Prof. J. G. McKendrick, M.D., LL.D., F.R.S.E., Professor of Physiology in the University of Glasgow, and in the Royal Institution of Great Britain; on Tuesday evening, September 25, at 8 p.m., a soirée; on Wednesday, September 26, the concluding general meeting will be held at 2.30 p.m.

THE number of members of the British Association who have announced their intention of being present at the proposed meeting at Montreal in 1884, continues to increase, and now exceeds 410. It is stated that Lord Rayleigh has accepted the presidency for the Canadian meeting.

PROF. HUXLEY has been elected a Foreign Member of the U.S. National Academy.

FROM a list of seven names proposed by the Incorporated Societies throughout the colony, the following gentlemen have been elected honorary members of the New Zealand Institute:—Sir William Thomson, F.R.S., Professor of Natural Philosophy, University of Glasgow; Dr. W. B. Carpenter, F.R.S., C.B., of London; and Mr. R. L. J. Ellery, F.R.S., Government Astronomer at Melbourne.

PROF. TYNDALL has resigned his position as Scientific Adviser to the Board of Trade and the Lighthouse Boards.

WE are glad to see the ample recognition of music during the present week by the conferring of knighthood on Messrs. Sullivan, Grove, and Macfarren in connection with the New College of Music. Let us hope that the science of music as well as the art will receive due cultivation in the new institution; with Sir George Grove's well-known wide sympathies, however, this may be taken for granted.

THE first eclipse news comes from Lima, under date May 7; the sky was overcast on the 6th, preventing any observation of the eclipse. It is to be hoped the conditions were more favourable on the other side of the Pacific.

THE proposal to open museums and galleries on Sundays was, we regret to say, lost in favour of Lord Shaftesbury's compromise to keep them open in the evenings on two or three nights a week, which does not in the least meet the case of the working classes.

M. RICHI, Professor in the Paris School of Medicine, was nominated Member of the Academy of Sciences on Monday, to fill the place vacated by the death of M. Sedillot. Another election will soon take place in the same section of medicine and surgery.

MR. A. H. KEANE proposes, as soon as he obtains a sufficient number of subscribers, to begin the publication of "A Classification of the Races of Mankind," copious materials for which have now been collected. It will form two large octavo volumes of about six hundred pages each. The publication will probably extend over two years, and at least five hundred names will be required to justify the undertaking, although subscribers to the first need not be committed to purchase the second part also. Subscriptions will be received by Mr. Edward Stanford, 55, Charing Cross, or by Mr. Keane, at University College, London. With regard to the scope and contents of the work, it may be briefly stated that its aim will be to place in the hands of the ethnological student a comprehensive treatise on the races of mankind harmonising with the present state of anthropological inquiry. In the general introduction such broad questions will be dealt with as the evolution of man, the antiquity and specific unity of the species, the present varieties of mankind, the physical and moral criteria of race, the fundamental human types, their evolution and dispersion, the peopling of the continents, the origin of articulate speech, the morphological orders and families of speech, the problem of specific linguistic diversity within the same ethnical group. The great physical divisions of the human family will then be dealt with *seriatim*, and here the same arrangement will be adhered to as that observed in Mr. Keane's ethnological appendices to the Stanford Geographical Series. Each of the main sections of mankind will thus be treated in three separate parts. In the first the salient physical and moral characteristics of the type will be discussed. The second will be occupied with the several main branches of each, and here the proper work of classification will be carried out in detail. Lastly, the third part will consist of an alphabetical index, comprising, as far as Mr. Keane has been able to collect them, all the known races, tribes, and languages of each main division, briefly described, and with copious references to authorities. The price of the work will be 16*s*. per volume to subscribers.

THE Dutch Polar ship *Willem Barents* started again on Saturday from Amsterdam, under the command of Capt. Dalen, for the Arctic regions, to try to discover the Dutch expedition in the *Varna*. Mr. Leigh Smith was present, as well as Mr. Clements Markham, to wish the *Willem Barents* "God speed." Sir Allen Young went over to express his best wishes to the crew of the Dutch ship. Mr. Leigh Smith presented to Capt. Dalen two magnificent silver cups, bearing as an inscription the following words, taken from his journal: "August 3d, 1882; Matotchkin Skarr, Nova Zembla, 10.0 a.m. A sail! A sail! The *Willem Barents*."

THE Danish expedition to Greenland left Copenhagen on Wednesday last week. Its purpose is to explore the east coast of Greenland; and it will probably be away for two years.

THE Sanitary Institute of Great Britain held its annual meeting at 9, Conduit Street, on Monday, Prof. de Chaumont, M.D., F.R.S., in the chair. A report was presented by the Council on the progress of the Institute and on the work at the Congress and Exhibition held by the Institute at Newcastle last autumn. The Chairman gave an address, and the officers for the ensuing year were elected, the President being the Duke of Northumberland, and the trustees Sir John Lubbock, Bart., Mr. Thomas Salt, M.P., and Dr. B. W. Richardson.

THE Prince of Wales opened the Indian Institute at Oxford last week.

Two divisions of the pupils of Sainte Barbe left Paris on May 4, one for London, and the other for Germany, where they are to stay for three months under the care of their professors, for the purpose of obtaining practical knowledge of the English and German languages.

REAR-ADMIRAL MOUCHEZ is leaving Paris within a few days. for Algiers, where he will establish an observatory at Coubar. This site is deemed excellent for observations.

WE have received the announcement of an aëronautical exhibition, to be held from June 5 to 15 at the Trocadéro, Paris.

THE Whit Monday excursion of the Geologists' Association will be to Hunstanton; and on May 26 to Ealing and Perivale.

THE well-known explorer of the fauna and depths of Lake Baikal, Dr. Godlevsky, who is now in Kamchatka, writes to the East Siberian Geographical Society, from Petropavlovsk, that last summer he transported on board of a steamer of the company Hutchinson, Kool, and Co., fifteen reindeer, of which eleven were males and four females, to Behring's Island. The reindeer were brought to Petropavlovsk from the west coast of Kamchatka in a flock of 150, and the journey took no less than two and a half months, as it was made across the mountains in order to avoid the mosquitos of the valleys. On board the steamer the reindeer were fed with stems and leaves of birch, as also with fresh grass kept in casks with water. Afterwards they also ate hay, and even bread, contrary to the affirmations of the Lamuts, who said that reindeer never eat grass that has been gathered by man. The steamer-journey was made in two days, and the reindeer arrived in good health.

WHEN leaving Yakutsk for the mouth of the Lena, M. Yurgens distributed a number of thermometers to different persons. The *Izvestia* of the East Siberian branch of the Russian Geographical Society now publish the meteorological observations made at Markha, in the province of Yakutsk, district of Viluisk, during the four months of August to November last, by an exile, M. Pavloff. The rapidity with which the cold weather sets in in those latitudes is very interesting. In August the thermometer rose at 1 p.m. as high as 31° Cels. (on August 1), and reached 14° to 20° during the second half of the month. The first frosts were experienced (at 7 a.m.) in September, and already in the first days of October the thermometer sunk (at 7 a.m.) as low as −11° to −20°; and as low as −30° to −35°, and even −39°, during the second half of October. In November it never rose above −32°, and usually stood at seven o'clock in the morning between −39° to −50°; even at 1 p.m. it did not rise, during the whole of the month, above −31°, and usually stood between −33° to −42°, occasionally sinking to −48° and −50° Cels. The underground thermometer, placed at 1·5 feet below the surface, decreased with a remarkable regularity, from 6°·8, on August 1, to 0° on September 12 to 17, to −2° on October 17, to −6° on November 1, and to −17° on November 30.

A CORRESPONDENT points out that at the conclusion of the address by Prof. Du Bois Reymond on "Darwin and Copernicus"

(NATURE, vol. xxvii. p. 558), it is stated that "Charles Darwin lies buried in Westminster Abbey among his peers, Newton and Faraday," whereas Faraday lies buried in the unconsecrated ground at Highgate, and not in Westminster Abbey.

ACCORDING to information received from the United States, some wonderful telephonic feats are being performed by the new Hopkins arrangement. It seems that two operators—one at New York and the other at Chicago, 1100 miles apart—had no difficulty, not only in talking to each other, but in listening to music, and fulfilling other tests. Even the noise produced by changing the diaphragm at New York was distinctly heard at Chicago.

THE Institute of Agriculture at South Kensington completed the work of its first session on Monday, the 7th inst. The Earl of Aberdeen, Chairman of the Council, presided, and distributed Certificates of Merit to 103 students. Notice was given of largely increased opportunities for study during the next session, which commences on October 1.

THE National Eisteddfod of Wales is not without an appreciation for science; in its list of prizes three are offered in natural history, one of 10*l.* 10*s.*, open to all comers, being for the best model of a skeleton of Plesiosaurus. Length of model not to be less than 4 feet, each bone to be separately modelled and removable except those of the cranium and phalanges. Competitors may obtain information and aid on application to Prof. Sollas, University College, Bristol.

THE statue of Leibnitz, intended for Leipzig, has recently been cast by Herr Lenz of Nuremberg, after the model of Prof. Hähnel, and the casting was a complete success. Herr von Miller of Munich has received an order for a colossal statue of Columbus, destined for the city of Cincinnati.

WE hear of a curious incident occurring on Siemens' electric railway at Portrush. Owing to the fact that as yet only part of the line is furnished with electric conductors, a steam-engine is still used as well as the electric locomotive. A few days ago the steam-engine while drawing its load along the line came to a stand through the accident of bursting a boiler-tube. News of the disaster having been sent to the terminus, the stationary dynamo-electric machine which supplies the current was set into action and the electric locomotive despatched to the rescue. It returned an hour later bringing the disabled steam-engine behind it.

M. FOUSSEREAU has lately measured the electric resistance of glass by charging a condenser from a known battery through a given thickness of the glass, and observing the time required to raise the potential of the condenser to a given degree. Bohemian glass was found to be from 5 to 20 times as good a conductor as ordinary glass, whilst flint glass was from 1000 to 1500 times as good an isolator. M. Foussereau found also that annealing the glass increased its resistance in some cases elevenfold.

AT a special general meeting of the Entomological Society of London, held on May 2, Prof. J. O. Westwood, M.A., F.L.S., was elected titular life-president of the Society by acclamation, the occasion being the fiftieth anniversary of the meeting at which steps were taken to establish the Society.

OUR readers will remember the accounts given last autumn of the electric launch which was successfully tried upon the Thames last autumn. This little craft has been running at intervals all the winter and is still in good trim. We learn that the Electrical Power Storage Company have three other electric boats on hand; one of them for the British Government.

A STRONG earthquake shock, with an undulating motion, was felt on the morning of the 8th, at Biancavilla, Sicily.

REPEATED shocks of earthquake were observed in various places in the Spanish province of Valencia on April 14 and 16. Some were of 2 to 3 seconds' duration.

LITERARY piracy would appear to be one of the institutions of the West to which young Japan has taken rather kindly. According to the *Japan Gazette*, the practice of pirating patents, stamps, and labels, in order to palm off spurious imitations for the genuine article, has been carried on for years, and the evil is extending in every direction. Recently a native company called the "Tokio Bookselling Company" was established in the capital, and its chief business appears to be the pirating of English and American schoolbooks. Todhunter's well known Elementary Algebra, Euclid, and other mathematical books have already been reproduced, as well as several American books, Mill's "Liberty," and other volumes. These are published as much like the originals in size, covers, &c., as possible. The Company affixes its imprint to the titlepages, but offers no explanation as to the publication in Japan, and indeed they have no hesitation in reprinting (probably through ignorance) the foreign publishers' notices, such as "Entered according to the Act of Congress in the year, &c., &c." An examination of the reprint of Todhunter's Algebra shows letters upside down, wrong fount letters, letters misplaced, and words improperly spelt, testifying to the slovenly way in which the books have been printed. There is said to be scarcely a page in the book which does not contain one or more errors in orthography, and the mathematical formulæ, which always require such care at the printers' hands, must be in a bad state when ordinary words are so neglected. The direct damage to foreign authors, patentees, and manufacturers by these petty thefts cannot be very great; the real injury is to the Japanese people themselves. Among well-known English labels, that of Bass and Co. has for many years been the subject of innumerable depredations. The striking red diamond on white ground lends itself easily to imitation, while to people who cannot read English letters at all, any strange marks below the diamond are sufficient to represent the names of the eminent brewers. Large quantities of some decoction brewed in Tokio are thus passed off in the interior as Burton ale. A patent law is wanted in Japan, not so much for the protection of foreign inventors (the Japanese Government is far too advanced to think of such a minor consideration as this) as for the protection of the pockets and stomachs of the Japanese themselves.

WE are pleased to observe that the *Chrysanthemum* magazine of Yokohama has commenced its third year with a more ambitious flight. The size is considerably enlarged, as is also the number of subjects treated and the staff of writers. The theological discussions appear to be wholly eliminated, to the increase of the general interest of the journal. The first two numbers of the new issue are now before us, and exhibit no lack of mental power. The literary treatment of the varied subjects discussed is in most cases excellent. The most powerful recruit appears to be Capt. Brinkley, R.A., who writes a serial tale with Japanese characters and scenes, as well as a serial history of Japanese keramics, which deserves more attention in this country than it is likely to get. Higher education in Japan is elaborately treated by Dr. Groth, while Capt. Blakiston, probably the best authority on the ornithology of Japan, writes on that subject. Mr. A. H. Cole is responsible for a popular paper on the Darwinian theory, and Prof. Summers describes some ancient caves near Osaka. These are but a few of the papers in the first numbers of the new magazine, the editor of which appears determined at least to deserve success. We may, however, draw his attention to one defect, surely a very grave one in a scholarly publication such as this, viz. the notices of current literature, which so far have been quite unequal to the other departments.

THE additions to the Zoological Society's Gardens during the past week include a Macaque Monkey (*Macacus cynomolgus*) from India, presented by Mrs. Florence A. Hill ; a Common Rhea (*Rhea americana*) from Uruguay, presented by Mr. F. R. S. Balfour ; a Common Kestrel (*Tinnunculus alaudarius*), British, presented by Mr A. Lidbury ; a Wood Owl (*Syrnium aluco*), British, presented by Mrs. W. Duncan ; two Horned Lizards (*Phrynosoma cornutum*) from Texas, presented by Mr. John G. Witte ; two Marbled Newts (*Triton marmorata*) from France, presented by Mr. G. H. King ; two Viverrine Cats (*Felis viverrina*), an Indian Otter (*Lutra nair*), an Indian Darter (*Plotus melanogaster*), a Hamilton's Terrapin (*Clemmys hamiltoni*), three Indian Gazelles (*Gazella bennetti*) from India, deposited ; two Natterjack Toads (*Bufo calamita*), four Marbled Newts (*Triton marmorata*), four Short-nosed Sea Horses (*Hippocampus antiquorum*), from France, purchased ; a Black Wolf (*Canis niger*) from India, received in exchange ; an Eland (*Oreas canna* ♀), born in the Gardens.

OUR ASTRONOMICAL COLUMN

D'ARREST'S COMET.—Although M. Leveau's elements of this comet for the approaching return to perihelion were communicated to the Academy of Sciences of Paris on January 22, they were unaccompanied by predicted places, and it would appear that the ephemeris has had only a very limited circulation, being confined, if we are rightly informed, to those observers who are in possession of the larger instruments. Hence comparatively few persons may have become acquainted with the circumstances under which this return of the comet to perihelion takes place, and it may not be without interest if we briefly examine the conditions as compared with those of former appearances.

Assuming as usual the intensity of the comet's light (I) to be represented by the reciprocal of the product of the squares of the distances from the earth and sun, we find the following values :—

		I.
1851.	Last observation at Berlin, Oct. 6	0·590
1858.	Last observation at the Cape, Jan. 18 ...	0·151
1870.	Last observation at Athens, Dec. 20 ...	0.154
1877.	Last observation at Athens, Sept. 10 ...	0·127

The greatest distance from the earth at any of these dates was 1·93 on January 18, 1858.

M. Leveau's elements for the approaching return apply to 1883, June 12·0 M.T. at Paris ; neglecting, of course, the small effect of perturbation in the interval, the perihelion passage is found to take place 1884, January 13·5765 M.T. at Greenwich. The coordinate constants for apparent eqt inox of 1883, May 1, are :—

$$x = r\,.\,[9{\cdot}99502] \sin (v + 50^\circ\ 13'{\cdot}7).$$
$$y = r\,.\,[9{\cdot}99308] \sin (v + 321\ 48{\cdot}0).$$
$$z = r\,.\,[9{\cdot}36631] \sin (v + 280\ 38{\cdot}1).$$

Hence we have the following approximate positions and distances of the comet, with the corresponding values of the theoretical intensity of light, taking dates near the time of new moon :—

12h. G.M.T.	R.A. h. m.	Decl. ° ′	Distance from Earth.	Distance from Sun.	I.
June 6 ...	13 9·6 ...	-12 48 ...	2·037 ...	2·615 ...	0·035
July 4 ...	13 13·7 ...	+10 12 ...	2·185 ...	2·415 ...	0·036
Aug. 2 ...	13 37·0 ...	+ 5 42 ...	2·321 ...	2·204 ...	0·038
Nov. 29 ...	17 58·6 ...	−16 55 ...	2·281 ...	1·427 ...	0·094
Dec. 29 ...	19 45·7 ...	−18 8 ...	2·244 ...	1·338 ...	0·111

Whence it will be seen that even when most favourably circumstanced, towards the end of the year, the intensity of light will be less than the lowest value at which the comet has hitherto been observed, viz. 0·127. On November 29 the comet sets about 2h. 8m. after the sun. It was missed at the return in 1864, and the chances of observation at its present visit are by no means encouraging.

Mr. Common informs us that he has made a thorough search or the comet with his large reflector, but without success up to May 7. He remarks that the number of faint nebulæ about its track is surprising.

The orbit of this comet almost intersects that of the lost comet of De Vico, 1844 ; in heliocentric longitude 339°·37′, with the elements of 1851, the distance between the orbits was only 0·0055 or 507,000 miles.

TEMPEL'S COMET, 1873 II.—The corrected elements of this body by M. Schulhof, from observations at its last appearance in 1878, indicate that, neglecting perturbations, it may be again in perihelion about November 20. The positions calculated on this assumption show that the comet will be very unfavourably placed for observation, and it may escape detection at this return.

RULES AND REGULATIONS FOR THE PREVENTION OF FIRE RISKS ARISING FROM ELECTRIC LIGHTING[1]

THESE rules and regulations are drawn up for the reduction to a minimum, in the case of electric lighting, of those risks of fire which are inherent in every system of artificial illumination, and also for the guidance and instruction of those who have, or who contemplate having, electric lighting apparatus installed on their premises.

The difficulties that beset the electrical engineer are chiefly internal and invisible, and they can only be effectually guarded against by "testing," or probing with electric currents. They depend chiefly on leakage, undue resistance in the conductor, and bad joints, which lead to waste of energy and the dangerous production of heat. These defects can only be detected by measuring, by means of special apparatus, the currents that are either ordinarily or for the purpose of testing, passed through the circuit. Should wires become perceptibly warmed by the ordinary current, it is an indication that they are too small for the work they have to do, and that they should be replaced by larger wires. Bare or exposed conductors should always be within visual inspection and as far out of reach as possible, since the accidental falling on to, or the thoughtless placing of other conducting bodies upon such conductors, would lead to "short circuiting," and the consequent sudden generation of heat due to an increased current in conductors not adapted to carry it with safety.

The necessity cannot be too strongly urged for guarding against the presence of moisture and the use of "earth" as part of the circuit. Moisture leads to loss of current and to the destruction of the conductor by electrolytic corrosion, and the injudicious use of "earth" as a part of the circuit tends to magnify every other source of difficulty and danger.

The chief dangers of every new application of electricity arise from ignorance and in:xperience on the part of those who supply and fit up the requisite plant.

The greatest element of safety is therefore the employment of skilled and experienced electricians to supervise the work.

I. THE DYNAMO MACHINE

1. The dynamo machine should be fixed in a dry place.
2. It should not be exposed to dust or flyings.
3. It should be kept perfectly clean and its bearings well oiled.
4. The insulation of its coils and conductors should be practically perfect.
5. All conductors in the dynamo room should be firmly supported, well insulated, conveniently arranged for inspection, and marked or numbered.

II. THE WIRES

6. Every switch or commutator used for turning the current on or off should be constructed so that when it is moved and left it cannot permit of a permanent arc or of heating.

7 Every part of the circuit should be so determined, that the gauge of wire to be used is properly proportioned to the currents it will have to carry, and all junctions with a smaller conductor should be fitted with a suitable safety fuse or protector, so that

[1] Recommended by the Council of the Society of Telegraph Engineers and of Electricians in accordance with the Report of the Committee appointed by them on May 11, 1882, to consider the subject. Members of the Committee:—Prof. W. G. Adams, F.R.S., Sir Charles T Bright, T. Russell Crampton, R. E. Crompton, W. Crookes, F.R.S., Warren De La Rue, D.C L., F.R.S., Prof. G C Foster, F.R.S., Edward Graves, J. E. H. Gord)n, Dr. J. Hopkinson, F.R.S., Prof. D. E. Hughes, F.R.S., W. H. Preece, F.R.S., Alexander Siemens, C. E. Spagnoletti, James N. Shoolbred, Augustus Stroh, Sir William Thomson, F.R.S., Lieut.-Col. C. E. Webber, R.E.

no portion of the conductor should ever be allowed to attain a temperature exceeding 150° F.

8. Under ordinary circumstances complete metallic circuits should be used; the employment of gas or water pipes as conductors for the purpose of completing the circuit should not in any case be allowed.

9. Bare wires passing over the tops of houses should never be less than seven feet clear of any part of the roof, and all wires crossing thoroughfares should invariably be high enough to allow fire-escapes to pass under them.

10. It is most essential that joints should be electrically and mechanically perfect and united by solder.

11. The position of wires when underground should be clearly indicated, and they should be laid down so as to be easily inspected and repaired.

12. All wires used for indoor purposes should be efficiently insulated, either by being covered throughout with some insulating medium, or, if bare, by resting on insulated supports.

13. When these wires pass through roofs, floors, walls, or partitions, or where they cross or are liable to touch metallic masses, like iron girders or pipes, they should be thoroughly protected by suitable additional covering; and where they are liable to abrasion from any cause, or to the depredations of rats or mice, they should be efficiently incased in some hard material.

14. Where indoor wires are put out of sight, as beneath flooring, they should be thoroughly protected from mechanical injury, and their position should be indicated.

N.B.—The value of frequently testing the apparatus and circuits cannot be too strongly urged. The escape of electricity cannot be detected by the sense of smell, as can gas, but it can be detected by apparatus far more certain and delicate. Leakage not only means waste, but in the presence of moisture it means destruction of the conductor and its insulating covering, by electric action.

III. Lamps

15. Arc lamps should always be guarded by proper lanterns to prevent danger from falling incandescent pieces of carbon, and from ascending sparks. Their globes should be protected with wire netting.

16. The lanterns, and all parts which are to be handled, should be insulated from the circuit.

IV. Danger to Person

17. Where bare wire out of doors rests on insulating supports, it should be coated with insulating material, such as india-rubber tape or tube, for at least two feet on each side of the support.

18. To secure persons from danger inside buildings, it is essential so to arrange and protect the conductors and fittings that no one can be exposed to the shocks of alternating currents of a mean electromotive force exceeding 100 volts, or to continuous currents of 200 volts.

19. If the difference of potential within any house exceeds 200 volts, the house should be provided with a "switch," so arranged that the supply of electricity can be at once cut off.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE

Cambridge.—Dr. Humphry has formally resigned the Professorship of Anatomy, after having taught anatomy in the University for thirty-six years, at first as assistant to Prof. Clark, and since 1866 as Professor. The Electoral Board for the Professorship consists of Professors Huxley, Allen, Thompson, Flower, Paget, Newton, and Liveing, Dr. Michael Foster, and Mr. J. W. Clark.

The Honorary Degree of LL.D. will be conferred in June upon Count Menabrea, formerly Italian Ambassador to England, Prof. Pasteur, Prof. Michaelis (Strasburg), Sir A. Grant, Bart., Principal of Edinburgh University, Sir John Lubbock, Bart., Sir J. A. G. Ouseley, Bart., Professor of Music at Oxford, Sir Richard Temple, Bart., Lieut.-Gen. Walker, Surveyor-General of India, Mr. Matthew Arnold, Prof. W. W. Goodwin (Harvard, U.S.), Mr. Reginald S. Poole (British Museum), Prof. H. E. Roscoe (Owens College), and Mr. G. F. Watts, R.A.

The Graces creating a Professorship of Surgery without stipend, and authorising the immediate appointment of a Professor of Physiology, are to be voted on to-day (Thursday).

The City and Guilds of London Institute has decided to make a grant of 300*l*. a year for five years, for the purpose of supporting a Chair of Mechanical Engineering in connection with Firth College, Sheffield.

SOCIETIES AND ACADEMIES

London

Royal Society, March 15.—"Atmospheric Absorption in the Infra-Red of the Solar Spectrum." By Capt. Abney, R.E., F.R.S., and Lieut.-Col. Festing, R.E.

Any investigations on the subject of atmospheric absorption are of such importance in the study of meteorology, that we have deemed it advisable to present a preliminary notice of certain results obtained by us, without waiting to present a more detailed account which will be communicated at a future date. From 1874, when one of us commenced photographing the spectrum in the above region, till more than a year ago, the extremely various manners in which the absorption took place caused considerable perplexity as to their origin, and it was only after we had completed our paper on the absorption of certain liquids [1] that a clue to the phenomena was apparently found. Since that time we have carefully watched the spectrum in relation to atmospheric moisture, and we think that more than a year's observations in London, when taken in connection with a month's work at an altitude of 8500 feet on the Riffel, justify the conclusions we now lay before the Society.

A study of the map of the infra-red region of the solar spectrum,[2] and more especially a new and much more complete one, which is being prepared for presentation to the Royal Society by one of us, shows that the spectrum in this part is traversed by absorption lines of various intensities. Besides these linear absorptions, photographs taken on days of different atmospheric condition show banded absorptions superposed over them. These latter are step by step absorptions increasing in intensity as they approach the limit of the spectrum at the least refrangible end. In the annexed diagram [3] Fig. 4 shows the general appearance of this region up to λ 10,000 on a fairly dry day: the banded absorption is small, taking place principally between λ 9420 and λ 9800: a trace of absorption is also visible between λ 8330 and λ 9420. On a cold day, with a north-easterly wind blowing, and also at a high altitude on a dry day, these absorptions nearly if not quite disappear. If we examine photographs taken when the air is nearly saturated with moisture (in some form or another) we have a spectrum like Fig. 1. Except with very prolonged exposure no trace of a spectrum below λ 8330 can be photographed. Fig. 2 shows the absorption-bands, where there is a difference of about 3° between the wet and dry bulbs, the latter standing at about 50°. It will be noticed that the spectrum extends to the limit of about λ 9420, when total absorption steps in and blocks out the rest of the spectrum. Fig. 3 shows the spectrum where the difference between the wet and the dry bulbs is about 6°. Figs. 5 and 6 show the absorption of thicknesses of 1 foot and 3 inches of water respectively, where the source of light gives a continuous spectrum. With ½-inch of water all absorption-bands except that commencing at λ 9420 are absent. It will be seen that there is an accurate coincidence between these "water-bands" and the absorption-bands seen in the solar spectrum, and hence we cannot but assume that there is a connection one with the other. In fact, on a dry day it is only necessary to place varying thicknesses of water before the slit of the spectroscope and to photograph the solar spectrum through them, in order to reproduce the phenomena observed on days in which there is more or less moisture present in the atmosphere. It is quite easy to deduce the moisture present in atmosphere at certain temperatures by a study of the photographs. There does appear a difference, however, in the intensity of the banded absorptions in hot weather and in cold about up to 50°. In the former they are less marked when the degree of saturation and the length of atmosphere traversed are the same as in the latter.

The accepted view, we believe, of absorption of vapours is that they give linear absorptions in certain thicknesses, and as the thickness increases or the density becomes greater, the lines

[1] "The Influence of the Atomic Groupings of the Molecules of Organic Bodies on their Absorption in the Infra-Red Region of the Spectrum." *Phil. Trans.*, Part III., 1881.

[2] *Phil. Trans.*, 1880.

[3] The black lines given in the diagram are merely lines of reference, and do not represent the aqueous absorption under consideration.

blacken, new lines appear, and gradually total absorption sets in in the region where the lines are most numerous and close. It is in the range of possibility that the presence of a small quantity of vapour might show itself as a haze over some region of the spectrum; if, however, the quantity was gradually increased, the haze would give place to lines, and the phenomena just described would be repeated. Suppose several localities of absorption to exist, the absorptive power of the vapour increasing the further down in the infra-red the locality was situated, it might happen that, whilst one locality showed only a haze of absorption, one further down might show total absorption, and some locality between these two should show linear absorption.

In the case of the absorptions in the solar spectrum we find a very different state of things existing. A comparison of the photographs taken in London on days of different dryness, and with those taken at the Riffel, shows that the linear absorptions are not increased in number or intensity; except so far that the blackness of the lines is increased by the blackness of the banded absorptions, and the same blackness can be induced by placing a certain thickness of water before the slit of the spectroscope: another point is that the Fraunhofer lines in certain regions (say λ 9420 to λ 9800) are so irregularly distributed as to preclude the idea that they all belong to the absorption of aqueous vapour, yet all are equally darkened by the band, and they do not spread out as the blackness of the band increases. This is against the view of the bands being formed by aqueous vapour, as we know it.

The question then arises as to what these "water-bands" can be due—if not due to vapour. This we consider an open question, and one which should be discussed. All we can state is that the absorptions shown are similar to those of water (liquid) and they do not seem to point to the watery stuff existing as vapour,[1] if we take the visible spectrum as a guide. An intense blue sky at sea-level is often indicative of moisture in the atmosphere, and it also seems to be indicative of finely suspended matter of some kind. If this be the case, can this suspended matter be suspended water stuff? for if it be not, there is no reason why the sky should be bluer on a moist day than on a dry day. We would remark that the deep blue sky at sea-level is of a different colour to the black-blue of high altitudes where, if they exist, the fine suspended particles would be largely diminished in number, and the coarser particles which cause white haze would also be fewer. The great difference of

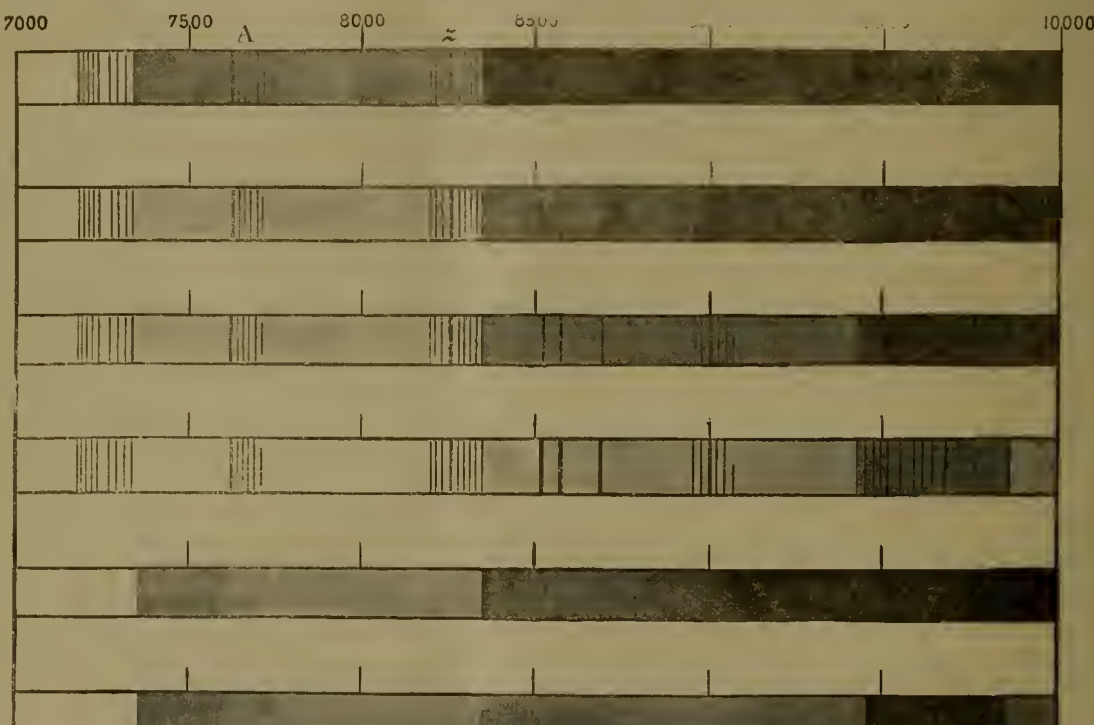

FIG. 1.

FIG. 2.

FIG. 3.

FIG. 4.

FIG. 5.

FIG. 6.

the intensities of the light from the blue sky in England and at 10,000 feet was determined by one of us and communicated to the British Association at Southampton, and the enormous disparity between the two has some bearing on the question we have been discussing.

In the above paper we have described the absorption due to "water stuff" in the atmosphere to λ 9800, as it is only to that wave length to which the normal spectrum has been as yet published. We wish however to add that there are bands in the solar spectrum commencing at[1] λ 9800, λ 12,200, and λ 15,200, and giving step by step absorptions from one wave-length to the next, as in the diagram, which also corresponds with *cold* water bands. The absorption in the locality from 12,200 downwards is usually total, and it is only on dry cold days or at high altitudes that rays of sufficient amplitude can penetrate to cause photographic impression to be made.

April 5.—"Observations on the Colouring-matters of the so-called Bile of Invertebrates, on those of the Bile of Vertebrates, and on some unusual Urine Pigments, &c.," by Charles A. MacMunn, B.A., M.D. Communicated by Dr. M. Foster, Sec.R.S.

In this paper the result of a systematic examination of the bile and various extracts of the so-called liver of Mollusca and Arthropoda, and of the pyloric or radial cœca and other appendages of the digestive system of Echinodermata is described. The universal distribution of one colouring-matter, which by appropriate experiments is shown to be a chlorophyll pigment, is proved. It occurs in the above organs, and can be detected in the bile of specimens of *Helix* after a six months' fast; for this colouring-matter, since it is found in the appendages of the enteron, the name enterochlorophyll is proposed. The slight differences observable in different cases are shown to be due to the probable greater or less amount of the usual chlorophyll constituents, blue chlorophyll, yellow chlorophyll, and chlorofucine, and the presence of xanthophyll, lutein, or tetronerythrin. Enterochlorophyll is shown to be much more abundant in the liver of Mollusca and in Echinodermata than in Crustacea, as the livers

[1] Unless it be held that the water itself holds vapour in solution.

[1] These wave-lengths are taken from the map from the *Phil. Trans.*, 1880, and are only to be considered approximate.

of the last generally contain more lutein, or sometimes tetronerythrin may be present.

The presence of reduced hæmatin is also demonstrated in the bile of the crayfish and in several pulmonate Mollusca, and its respiratory and other uses discussed.

The conclusions which these observations and others led to are summed up as follows :—

(1.) The existence of enterochlorophyll in the so-called liver, or other appendages of the enteron in Invertebrates is definitely established.

(2.) This pigment occurs in greatest abundance in Mollusca, it occurs less frequently in Arthropoda, and its presence in Vermes is not proved.

(3.) The pyloric cœca of starfishes contain it in great abundance, also the intestinal appendages of *Echinus*, which fact shows that the former function like the so-called liver of other Invertebrates.

(4.) The bile of the crayfish and that of most pulmonate Mollusca contains hæmochromogen ; in the latter it is generally accompanied by enterochlorophyll, and appears to be concerned more in aërial than aquatic respiration.

(5.) The so-called liver of Invertebrates is a pigment-producing and storing organ, as well as being concerned in the preparation of a digestive ferment.

(6.) The presence of hæmochromogen in the bile of Invertebrates is apparently determined by their mode of living, and it does not appear to be distributed according to purely morphological considerations.

The remainder of the paper deals with vertebrate bile pigments, and contains some observations on abnormal urinary colouring matters, mainly with regard to their spectroscopy. The various bile pigments of Städeler are first dealt with, and some remarks on the bile spectra of animals follow ; here it is shown that urobilin can be extracted from the liver of *Salamandra maculata* by means of alcohol, that it is absent from reptilian bile during hibernation, and that the liver of some fishes may contain tetronerythrin which can be extracted from them by suitable solvents. The latter fact suggests an analogous function to that of the liver of Invertebrata.

The results of the examination of a green hydrocele liquid are detailed, which showed beyond doubt that biliverdin was present, and since in that case its origin could be traced to blood pigment, the origin of biliverdin from blood pigment is demonstrated.

The identity of stercobilin and hydrobilirubin got by the action of nascent hydrogen on bilirubin is proved, and a difference between them and febrile urobilin shown to exist.

The statement that the absorption-bands of sheep bile are the same as those which occur in Gmelin's reaction is shown to be erroneous, and a brief description of the method of isolating the colouring-matter of sheep bile and the wave-lengths of its different solutions given. Chlorophyll is shown to be absent.

Under the head of urinary pigments it is shown that the feeble bands described by me in a former paper in the spectrum of febrile urobilin are not due to impurities, but are as much part of the spectrum as the band at F. Urohæmatin and its difference from hæmatoporphyrin and its pathological significance are discussed. A simple method for the detection of indican in urine, some remarks on uroerythrin, and on a peculiar red colouring-matter in pale urine, somewhat like urrhodin, follow. The deductions from this part of the paper cannot be very well given in the form of conclusions, and are therefore scattered throughout the paper.

A drawing of the microscopic structure of the liver of Limax, showing the enterochlorophyll within the liver cells, and maps of the most important absorption spectra described, accompany the paper. All readings are reduced to wave-lengths.

Physical Society, April 28.—Prof. Clifton in the chair.—A paper on colour-sensation, by Mr. H. R. Troop, was read by Mr. Walter Baily, secretary. The author showed that more than three colour-sensations were consistent with the theories of Maxwell and Helmholtz, and explained that four primary separate colour-sensations, in couples, served the theory as well as three. The author gave reasons for the existence of a fifth sensation—that of white. Mr. Stanley mentioned that his father was colour-blind to green, and saw it as a brown. He considered partial colour-blindness very common. Mr. Lewis Wright stated that he found in optical experiments a partial colour-blindness from time to time, and between one of his eyes and the other. He recommended the study of this partial and variable blindness to colours. Prof. Clifton stated that he had found similar variations amongst his students, and considered that one in three was unfit for delicate optical experiments.—Sir John Conroy exhibited a new photometer, which is a modification of Ritchie's, the white screens not meeting at an angle, but almost meeting, and one projecting a little beyond the other, so that the eye could see the outer side of one and a little of the inner side of the other, both visible surfaces being illuminated by the lights. The screens were inclosed in a blackened box.—Mr. Walter Browne then read a paper on the causes and consequences of glacier motion. After reviewing the various theories of glacier motion and criticising each, the author gave reasons for preferring that of Mr. Moseley, namely, expansion by heat. He showed that the regelation theory now commonly accepted appears inadequate, inasmuch as it does not explain the state of flow at low temperatures. Mr. Stanley pointed out that Forbes in his work on Norway gives expansion as a cause of glacier motion. Prof. Perry referred to the experiment of Mr. Bottomley (in which a wire, weighted at the ends, cuts its way through a block of ice) in support of the regelation theory ; and Prof. Guthrie described an experiment he had made of the same kind, using a copper wire and a silk cord of the same thickness, equally weighted, on the same block of ice. The wire cut through, but the silk did not. Prof. Ayrton explained this on the assumption that the wire conveyed heat from the air, and enabled the weighted wire to lower the temperature of the ice to the melting point, whereas the silk could not do so without more pressure, that is weight. Mr. W. Coffin referred to the ice-houses of Lake Superior, where he has seen heavy iron implements lying on blocks of ice at a low temperature, without sinking in. Sinking took place when the sun shone on the ice. Prof. G. Forbes said that below forty feet in rock variations of temperature were imperceptible, and probably it was the same with ice. Prof. Macleod, Mr. G. R. Griffiths, Mr. W. Baily, and the President also took part in the discussion.—Prof. Fuller then took the chair, and Prof. Clifton exhibited a new spectrometer of his design. In the spectrometer it is important that the axis round which the prism turns and the axis round which the telescope turns should not be inclined, and in the new instrument these axes are coincident. A single cone, turned very true, has the telescope piece, the circle, and prism plate fixed upon it.

Institution of Civil Engineers, April 24.—Mr. Brunlees, president, in the chair.—The paper read was "Resistance on Railway Curves as an Element of Danger," by Mr. John Mackenzie, Assoc. M. Inst. C.E.

Berlin

Physiological Society, March 30.—Prof. Du Bois Reymond in the chair.—Instead of the condensed milk, which, owing to its large percentage of sugar, has not kept its place as a food for children, a preparation of milk has lately been introduced into the market from Switzerland, which is protected against fermentation and decomposition by previous cooking. Dr. A. Baginski has chosen the relation of this new infants' food to the digestive ferments as the subject of a comparative investigation, which is not as yet concluded, but which has elicited some physiologically interesting facts about the action and occurrence of these ferments. The rennet ferment is well known to act upon milk both when it is sour and when its reaction is neutral or alkaline, but the rapidity of the curdling when acted upon by the ferment is different for different temperatures. At the temperature of the room the milk curdled only after twenty or thirty minutes ; at a temperature of 20° to 25° C. the curdling was already completed in five minutes ; at from 30° to 35° C. the curdling lasted about one minute, and it took place at still higher temperatures up to 55° C. in still shorter time. On the other hand, at 60° C. and at higher temperatures the action of the rennet was delayed, and soon ceased altogether. In previously boiled milk rennet also failed to bring about curdling. The rennet ferment was found not alone in the stomach, but also in the small intestines and in several plants, *e.g.* in *Carica papaya*, in artichokes, and in figs. In other plants it was sought for in vain. Decomposition ferments had various actions upon rennet ; sometimes they destroyed its action, at other times they did not ; the former was particularly the case when the fluid was strongly alkaline. Pepsin had no disturbing influence upon the activity of the rennet, although trypsin had to a marked degree. Dr. Baginski made similar observations upon the effect of decomposition ferment, pepsin, and trypsin upon each other.—Prof.

Brieger reported upon the results of his attempts at a more accurate study and determination of the violent poisons which develop out of animal substances, and which not unfrequently bring about sudden death after eating stale cheese, stale sausage, or stale fish. Prof. Selmi made the first step towards the knowledge of these poisons by preparing powerfully acting bodies out of corpses and decomposing animal matter. These he described under the name of "ptomäin." Prof. Brieger has now investigated their occurrence in analogous substances by means of the reactions that Prof. Selmi gave for these ptomäins, and he has found, among other things, that neurin when exposed to the air very soon develops such a ptomäin, which, like the rest, kills frogs and rabbits with the symptoms of coma. If the neurin remains a long time exposed to the oxidising influence of the air, the violent poison disappears. Further, a poisonous body belonging o the same group was found in a number of artificial peptones, but not in all, and here also this substance was soon destroyed by further alterations taking place in the peptone. This fact could be quite universally established, viz. that a further progressing decomposition in dead bodies destroyed all poisonous substances. Prof. Brieger next approached the task of isolating these easily decomposable and violently poisonous bodies. He succeeded, by working on large masses of dead animal bodies with a series of chemical processes, in preserving the poison in beautiful, large, needle-shaped crystals. He has not as yet determined whether these consist of the poisonous body pure, or whether they also contain other bodies. Therefore the chemical composition of the ptomäins has not yet been certainly determined.

PARIS

Academy of Sciences, April 30.—M. Blanchard in the chair.—The following papers were read:—On the reduction of the barometer and the pendulum to the sea-level, by M. Faye. While Poisson's correction for attraction of a continental mass may be suppressed, the attraction of a hill or mountain on which observations are made must not be neglected. At a station in mid-ocean, such as a volcanic or coral island, the attraction of the island must be considered. Correction for masses like the Alps or Himalayas is much more difficult.—On the pyro-electricity of quartz, by MM. Friedel and Curie. They dissent from Herr Hankel's views as to the distribution of electric tensions in crystals.—On a quaternary base derived from oxyquinoleine, by M. Wurtz.—Prolonged anæsthesia obtained by protoxide of nitrogen at normal pressure, by M. Bert. The new method he has tried on animals is to cause anæsthesia first with the pure protoxide, then give a mixture of the protoxide and oxygen (the blood then recovering the oxygen necessary to it); then the pure protoxide may be given again. Thus both asphyxia and return to sensibility are obviated. A dog was kept insensible half an hour. A mask and two caoutchouc bags are all that is necessary.—On the project of the African interior sea, by M. de Lesseps. He replies to M. Cosson.—On a theorem of partitions of complex numbers contained in a theorem of Jacobi, by Prof. Sylvester.—*Résumé* of meteorological observations made during the year 1882, at four points of Haut Rhin and the Vosges, by M. Hirn. *Inter alia*, the greatest actinometric differences do not always correspond to the most limpid skies. The slight mist or dust, which stops part of the luminous rays, does not absorb the calorific rays.—A new general formula for the development of the perturbative function, by M. Baillaud.—Observations of solar spots and faculæ at the Royal Observatory of the Roman College during the fourth quarter of 1882, by M. Tacchini. After the secondary minimum in August, the spots increased to a considerable maximum (relatively) in November, then decreased suddenly to a minimum in December. During 1882 there appears a greater activity than in 1881. The mean of faculæ is slightly greater in 1881 than in 1882.—Observations of solar protuberances, faculæ, and spots at the Royal Observatory of the Roman College, during the third and fourth quarters of 1882, by the same. The number of protuberances *per diem* was nearly the same as in the first half-year, but the height and extension were somewhat greater. The minimum was in September and October. Spots, faculæ, and protuberances were more numerous near the equator than in the previous half-year.—Observation of the transit of Venus at St. Thomas in the Antilles by the Brazilian Commission, by M. de Teffé. The third and fourth contacts were observed.—On the use of a birefringent glass in certain observations of spectrum analysis, by M. Cruls. By giving the crystal an alternative motion of rotation the extraordinary spectrum is displaced, and the eye is thus helped to see peculiarities better than if the spectrum were at rest. Again, the two spectra of a faint star may be so juxtaposed that the bright parts of the one correspond to the dark channellings of the other, so that vision is aided.—Determination of a particular class of surfaces, &c. (continued), by M. Darboux.—On continuous periodic fractions whose numerators differ from unity, by M. de Jonquières.—On the generalisation of the theorem of Fermat, by M. Lucas.—On the same, by M. Pallet.—On the groups of linear equations, by M. Poincaré.—On some double integrals, by M. Goursat.—On the Eulerian functions, by M. Bourguet.—On the cycle of motors with explosive gases, by M. Witz.—On the transmission of sound by gases, by M. Neyreneuf. With a sensitive flame arrangement he proves that carbonic oxide has about the same transmitting power as air; carbonic acid much greater. He finds Hauksbee's law inexact.—On the analogy that exists between the allotropic states of phosphorus and of arsenic, by M. Engel.—Research on the metallic derivatives of amides; means of distinguishing a monoamide from a diamide, by M. Gal.—On a process of hardening soft calcareous stones by means of fluosilicates with a base of insoluble oxides, by M. Kessler.—On a means of foreseeing liberations of firedamp, by M. de Chancourtois. On the supposition that movements of the earth's crust often cause such liberation, he proposes the use of delicate seismographic apparatus.—New histological researches on the termination of the biliary conduits in the lobules of the liver, by M. Kanellis.—On the structure of the nervous system of Hirudineæ, by M. Saint Loup.—On the incubation of eggs of a hen affected by cholera of fowls, by M. Barthélemy. The eggs contained germs of the microbes; these were only developed with aërial respiration when the allantoid yielded to the blood the oxygen necessary. (The development of the embryo stopped between the eighth and the tenth day.)—Comparison between the bacilli of tuberculosis and of leprosy (continued), by M. Babes.—M. Common presented a negative photograph of the nebula in Orion (taken January 30). An equatorial reflector of three feet aperture was used, and the dry plate was exposed 39 minutes.

THE FISHERIES EXHIBITION

"Do you know me, my lord?
Excellent well; you are a fishmonger."—*Hamlet.*

THE exhibition which was opened last Saturday by the Prince of Wales on behalf of Her Majesty the Queen is the latest of a series of such shows of matters relating to fish and fishing apparatus which was initiated by the French at Arcachon, other exhibitions having followed in subsequent years at Amsterdam, at Norwich, at Berlin, and at Edinburgh. Though in this country the accumulated knowledge and experience of scientific zoologists is not made use of either by the Government, or by local authorities, or by private capitalists in order to render our fisheries more productive, or to prevent the total destruction of some branches of them (except in the case of the salmon fisheries), yet the Fisheries Exhibition will have some interest for scientific men and for the readers of NATURE.

It is true that the present exhibition differs from its continental predecessors in the fact that it is a private undertaking entirely organised by practical men who would disclaim the title of "scientific" for themselves, and who have not largely availed themselves of the services of the professional zoologists of the country in carrying out their enterprise. Nevertheless the exhibition will have a scientific character and importance in consequence of the fact that almost without exception every foreign country which takes part in the exhibition is represented by distinguished zoologists, who have been delegated by the governments of the countries to which they belong, to take charge of and to organise the exhibition of such objects as in their judgment may best serve to illustrate the vast variety of matters of interest and instruction connected with their fisheries. From the republican United States of America, from democratic Norway, from Holland, from Sweden, and from Italy skilled zoologists have been sent by their respective Governments and are at this moment in London in order both to teach and to learn at the fisheries show.

It will be interesting to compare the results which these skilled officials and men of science can produce with those offered by the crowd of independent English exhibitors, manufacturers, fishery owners, fishmongers, and naturalists. Hitherto in the great fishery exhibitions England has been represented at a great disadvantage, for although the Governmental departments of fisheries control and inspection of foreign states have cordially responded to the invitation sent by the committee of the present London exhibition, yet on no occasion has the English Government assisted to place before the public in other countries any of the methods or products of English fishing. On the present occasion, though as hitherto the English Government has no official machinery for representing or dealing with British fisheries generally, and practically takes no part in the affair, yet in consequence of the activity of the large committee of gentlemen who have organised the exhibition, we shall no doubt see a much fuller representation of British fishing enterprise than at any former exhibition.

It is too soon at this moment, when many cases of objects are still unopened and sufficient time for a careful inspection of the exhibits has not elapsed, to offer any detailed remarks on the teaching to be derived from the fisheries show. On Saturday the special exhibit, which cannot be retained permanently during the whole period for which the show is open, was that of the fisherfolk themselves. Amongst the men the East Anglian herring fishers of Yarmouth and Lowestoft carried off the palm by their fine physique, intelligent faces, and sturdy bearing, wonderfully like to their brother Norsemen from the other side of the North Sea. These and the bright fearless faces of the Newhaven fisher-girls as they sat side by side with the strangely capped women from Boulogne and from the Dutch and Belgian coast, who good naturedly took part in the ceremony of Saturday last, were sufficient to demonstrate that whether British fisheries need or do not need to be improved and developed by that scientific supervision which is applied to the harvest of the sea on foreign shores, the race of men and women occupied in carrying on those fisheries bring to their business the fullest measure of intelligence and physical capacity. It is due to the courage, skill, and vigour of these fisherfolk that British fisheries continue to flourish, though their enterprise is unaided by the science of a Government department and their market is systematically injured by the devices of "middle-men."

Possibly the London Fisheries Exhibition of 1883 may have a result in regard to the British interests there represented similar to that which the Great Exhibition of 1851 effected in regard to the various art manufactures of the country. Just as the public demonstration of British inferiority in the matter of artistic workmanship led to the action of the Government in promoting a remedy in the foundation of schools of art and design, so the extraordinary contrast afforded by the British and Foreign exhibits on the present occasion in all that relates to a reasonable use of accurate knowledge (otherwise called science) in dealing with fish, oysters, lobsters, &c., may lead to an effort on the part of the constituted authority to imitate in some way the action of foreign governments (whether popular or paternal) in retaining the services of competent zoologists for the purpose of continually acquiring new knowledge in regard to fishes, and in particular of devising new ways of increasing and protecting the annual yield of fishes in the market.

It is a remarkable fact that for the purpose of dealing with questions and effecting practical objects connected with the economic aspects of the vegetable kingdom, the British Government supports the most efficiently organised botanical institution in the world. The Royal Gardens at Kew are the source of a ceaseless stream of scientific information and advice which is poured by every mail into all parts of the globe where our colonies extend, and it may be truly said that the pecuniary value of the scientific knowledge to British commercial enterprise, which has thus been furnished, is gigantic.

It does not admit of any question, that a parallel, though not in the first instance so vast a service, might be rendered to British industrial and commercial interests by a governmental zoological institution, to the scientific staff of which might be intrusted for study and control, not only matters relating to the sea- and river-fisheries of these

islands, our oyster, lobster, and shell-fish fisheries, but also matters concerning the pearl fisheries of India, the sponge-fisheries of the Bahamas, and the possible coral fisheries of the Australian coast. Further, the duties which even among the self-helping inhabitants of the United States are assigned to a State entomologist, might here also be discharged. From the duly established officials of such a state zoological laboratory or institute, the Foreign Office and the Colonial Office could at once obtain full and decisive information enabling them to act intelligently in relation to the importation of the Phylloxera pest, whilst the Home Office might gain courage in the presence of the Colorado beetle. It seems strange that the creation of an official laboratory of economic zoology has been so long delayed.

We shall be able to judge in the case of the present exhibition whether the cooperation of scientific men would have rendered the English department more instructive than it is under the present conditions, as compared with the scientifically organised exhibits of foreign countries. The comparison of the official catalogue of the London Exhibition with that of the Berlin Exhibition will be important in the same direction. With regard to the essays for which the committee has offered prizes, it may at once be stated that unfortunately no steps have been taken to bring the questions concerning which treatises are desired under the notice of the persons most likely to be able to deal with them satisfactorily either in this country or abroad. A series of valuable reports might have been obtained and circulated in connection with the exhibition by a sufficiently public appeal to the zoological world made in due time. It may yet be not too late to take some steps in this matter.

SCIENCE AND ART

NO one will be surprised that Mr. Huxley took advantage of the opportunity afforded him at the Academy dinner to reply to some remarks made by Mr. Matthew Arnold on a like occasion two years ago. Mr. Arnold, we presume, does not claim to possess that amount of knowledge either of art or of science which would render him a prejudiced witness, and, being unprejudiced, he drew a terrible picture of the future of art, not only in this, but in all other countries, unless some very decided steps were taken. Time out of mind, according to Mr. Arnold, art and literature had divided the sweets and beauties of this world between them, but now, in these latter days, that terrible thing science—

"Monstrum horrendum, informe, ingens, cui lumen ademptum,"

was about to bar their future progress, and invade and destroy the fair kingdoms of thought and work gained from the unknown by the labours of both. Hence the necessity of an alliance offensive and defensive against the common enemy; hence the artist and the man of letters were to band themselves together to stamp this new hydra from out the land.

It was not to be expected that such a view as this would be allowed to pass unchallenged by Mr. Huxley. He declined to regard science as an invading and aggressive power, eager to banish all other pursuits from the universe. Putting Mr. Matthew Arnold's view in a more concrete form, he represented it as picturing science rising as a monster from out the troubled waters of the sea of modern thought, intent upon devouring the unprotected Andromeda of Art. For him Literature was Perseus equipped with the swift shoes of the ready writer, and the cap of invisibility of the editorial article, while the death-dealing quality of Medusa's head had a fitting representative in the sting of vituperation. Mr. Huxley's remarks dealt less with Andromeda than with Perseus, to whom he suggested the advisability of thinking twice before trying conclusions with the risen monster. He ended by showing how necessary Art and Science were to each other, how each was strong in the other's strength, and how they were never likely to be sundered, but were certain to twine round each other more closely, and to help each other more as time went on. Agreeing as we do altogether with Mr. Huxley, we think, however, that another view is worthy of consideration. For ourselves, although likening art to fair and chained Andromeda, we cannot admit that science is correctly represented in the form of the monster. Without further considering of whom or of what the monster may be typical, it seems to us perfectly certain that the Perseus of whom the Andromeda of Art stands so much in need is not Literature, but Science, because this Perseus alone can give the help and render the assistance which the maiden needs so sorely at the present moment.

Occasion has been before taken in these columns to point out how one of the greatest revivals of art in the history of the world was contemporaneous with the dawn of one of those sciences which must for ever lie at the base of much work in art: we refer to the science of anatomy; and when one looks round this year's Academy and compares the work based upon this branch of knowledge, the anatomy of form, with that connected with the other branch of knowledge which has to do with the anatomy of light and colour, one cannot but feel that the Andromeda of Art is being sacrificed indeed. Landscape painting has as close a connection with physical science as figure painting has with anatomy, and we cannot help thinking it is because physical science has not been sufficiently taught in our public schools, that our landscape painting is, if we are to judge by this year's pictures, not advancing, but almost retrograding. The man who finds anatomy too difficult for him and rushes into landscape soon discovers that there is something there which he has not learned, but which has to be learned ere he can achieve distinction; and like too many others he has to give up the battle ingloriously. Not for many years has there been such an absence of landscapes of the highest order as in the present Academy; and in order to show, on the one hand, how those artists who have some knowledge of the branches of science which bear upon their work in art have succeeded in filling their canvases with worthy representations of natural effects, and, on the other hand, how those who lacking this knowledge are only successful in producing misrepresentations and distortions of nature, we shall on a subsequent occasion give a series of notes upon those pictures which fall within the reach of our remarks. In some pictures the ignorance of one part of nature has been as great as if a portrait painter had painted a face in which the mouth was represented between the eyes and

the nose, or again as if he had painted feet instead of hands.

There is one instance so much in point that we may at once refer to it. One artist, who shall be nameless, has attempted to grace his picture by introducing into it a rainbow. Now if the rainbow had been part of the human form it would have been studied, there would have been books about it, and the artist would have made it as much his own as the student of physical science, since some artists study anatomy as closely as does the man of medicine, but, because the rainbow happens to lie outside that branch of scientific knowledge which is generally supposed to be the only branch to which artists need turn their attention, the painter thinks that he may treat it anyhow. Thus we have had rainbows with the colours—which in nature are absolutely definite in their order and arrangement—painted in reverse order; again, we have had a rainbow, which must always appear to form part of a circle, painted in perspective; but the rainbow fancier of this year has almost transcended the want of observation shown by his predecessors. Possibly ignorant of the fact that all primary rainbows are alike; that the order of colours, from red through orange, yellow, green, blue, indigo, to violet, is dominated by a most rigid law, to which there is, and can be, no exception; the artist has chosen to paint his rainbow with the violet in the middle This seems to indicate either such looseness of observation or such contempt for nature—and the painter may take his choice between these two alternatives—that we doubt whether side by side with either there can exist that sympathy with nature which must lie at the root of all good work in art. We shall show on a subsequent occasion that this picture is only typical of a good deal of artistic work, which must in the nature of things act like a discord, and put the eye and the heart of the painter out of tune.

Those branches of science to which we have to make reference in these columns have to do of course with the forms and colours of clouds and sky and natural objects generally, and the laws of reflection, and if an artist will paint suns and moons, then with those elementary astronomical principles which have to deal with the appearances of these bodies, and which are not beyond the comprehension of a child in the Fourth Standard of a public elementary school. It is not therefore imposing too much upon an artist that he should know these things, and it is not too much to suppose that one who paints work on which he wishes to build his fortune or his reputation as the case may be, should wish to appeal to a more or less cultured audience. At present, perhaps, it is only a select few who notice and deplore this want of harmony with nature which marks the productions of so many of our artists; but the love of physical science among the great mass of mankind grows stronger and more strong, and the circle of those who can discriminate between fact and fancy as displayed in the works which grace the walls of our picture galleries is daily becoming a wider one. We would therefore utter a word of warning to the artist who allows blunders to creep into his picture because he thinks nobody will find them out. Somebody is sure to find them out.

The opportunities which artists in following their profession have of studying nature in very varied moods enable them to see the actual phenomena, where *a priori* considerations leave a student who lacks such opportunities entirely in the dark. Several very interesting questions are raised by some of the pictures in this year's Academy, and the candid critic must acknowledge that many of them give much food for thought and suggestions for future inquiry and study on his own part.

THE TRANSIT INSTRUMENT

A Treatise on the Transit Instrument as Applied to the Determination of Time; for the Use of Country Gentlemen. By Latimer Clark, M.I.C.E., &c. (Published by the Author.)

IT is something new to have a book on the transit instrument for the use of country gentlemen. It is something still newer to find that book brought out by an eminent engineer. In fact we may regard the publication of such a book, under such conditions, as a sign of the times, and as an indication of the slow but sure way in which science, and even the methods of science, are interesting a gradually increasing number of our educated classes. Mr. Latimer Clark has done his work in a most admirable manner, and no country gentleman who wishes to know a little more than he does at present about the practical working of a most fascinating branch of science, could do better than invest, not only in the book, but in the very satisfactory and handy little instrument which Mr. Clark has been wise enough to produce side by side with it. This transit instrument to which we refer, and which can be obtained of Mr. Coppock of Bond Street, is an excellent one of its kind. It is cheap—costing only about 10*l.*—and it is simple. The many parts of the instrument which form necessary adjuncts to it when used in an observatory are of course suppressed, but nothing is wanting which is really of importance to that public which Mr. Latimer Clark wishes to educate in its use The author is quite wise in the way he goes to work We naturally have a description of the instrument, and reference to the way in which it can be most conveniently and satisfactorily employed, nor are those necessary adjustments omitted without which of course the simplest instrument would be of very little use. Full instructions are then given for putting it in position, and Mr. Clark's form of instrument has a cover, by means of which, when once placed in position, say, out on a stone pillar on a lawn with a good north and south line, it can be left out with very little chance of its taking any harm in all weathers. The actual taking of transits, both of the sun and stars, are then dealt with, and we should add here that the transit eyepiece is armed with a system of seven vertical wires, so that the means of several transits over the wires can be taken in the ordinary way. The only objection we have so far found to Mr. Latimer Clark's form, is that there are no means of adjustment for the verticality of the wires. We regard this as a point which should be looked to, in case our author should be fortunate enough to induce a great many people to employ this cheap and simple form.

The corrections for longitude and latitude are next given, and we are glad to see that the book deals with these matters in a way not only far from dry, but so as to introduce a considerable quantity of very useful astro-

nomical knowledge put in a very simple and taking form. Thus, for instance, when Mr. Clark urges, and rightly urges, that the latitude of any particular house where it may be suggested to put up one of these instruments is more likely to be accurately determined by a reference to the Ordnance Map than in any other way, we are not only told that the Ordnance Map may be got for 1*s*., but the ignoramus is not even forgotten, and the way in which longitude is marked on the map is clearly stated. Mr. Clark it will be seen has spared no pains to make everything as clear as possible to everybody. Here, for instance, is what he says on counting time to a beginner in astronomical work:—

"In taking the time of transit by a watch some difficulty will at first be experienced, owing to the fact that watches tick various numbers of beats in a minute, but rarely any direct multiple of the second. Having carefully ascertained the number, the watch is placed to the ear at any even ten or twenty seconds, and the counting is continued by sound, thus: One and, one and, two and, two and, three and, three and, fifteen, fifteen, &c. In recording the transit, the minutes and seconds at the time of starting are noted, and the number of additional ticks is counted by ear, and these are afterwards converted into seconds and added. When a single observation is considered sufficiently accurate for practical purposes, it may be conveniently recorded by a chronograph, which is started in exact accordance with your clock a few minutes before it is required, and is stopped at the exact instant of transit. At night this dispenses with the necessity of referring to a lantern for time. These chronographs may now be obtained at a very moderate price, and when they beat quarter-seconds are very useful for counting, and for carrying the time of a clock or chronometer into the open air, and might be advantageously used on shipboard. The portable American clocks, which are sold everywhere for a few shillings, sometimes beat quarter-seconds, and serve well for counting time. They may be easily converted into rough chronographs by adding a stop movement in the form of a light spring pressing against the balance wheel; the second hands are, however, loose and inaccurate. A servant may be taught to record transits with the assistance of one of these chronographs very correctly.

"The writer, however, employs an arrangement which he considers still preferable. A rough pendulum about ten inches long is constructed out of a wire suspended by a flat spring or by a double loop of wire, and screwed at the bottom through a flat leaden plumb-bob; it is adjusted so as to beat half-seconds correctly. A very small glass bead or button is suspended loosely at the lower end of the rod, and strikes against a thin metal plate at each oscillation; it is started by a trigger of wood or wire, supporting the plumb-bob at a definite angle, and insuring uniformity of swing. This is fixed on a board and hung within reach of the instrument. It may be used in several ways; the trigger may be pulled at the instant of transit, the first tick being counted as one, and the counting being continued while the observer rises from his position, and obtains at leisure a coincidence with a given second on his watch, the number of beats being converted into seconds and deducted from the time noted. The observation is noted thus, 46m. 28-21, and is afterwards converted into

$$\begin{array}{rrr} 8^{\circ} & 46' & 28'' \\ & - & 10{\cdot}5 \\ \hline 8 & 46 & 17{\cdot}5 \end{array}$$

"Or the observer may start the pendulum just before the transit occurs, and having obtained a coincidence with his watch may continue to count by ear. The pendulum may, if preferred, be made to tick seconds by muffling one side of the metal strip with a piece of felt, and it may be removed after an observation, leaving the support and striking plate attached to the pillars of the transit. It oscillates on a rod or knife edge, and will continue in motion for two or three minutes."

As an appendix to the book we find transit tables giving the Greenwich mean time transit of the sun and certain stars for every day in the year, computed from the *Nautical Almanac*, and there is also a table for converting intervals of sidereal time into equivalent intervals of mean solar time. More recently the author has published a set of transit tables separately, and we would recommend those who use his book on the transit instrument to obtain them. To all who are not familiar with the use of the tables, clear and simple instructions are given, and we think they will prove of great use to those for whom they are intended.

Mr. Latimer Clark has certainly well deserved the thanks of all interested in astronomy, for the pains he has taken in thus endeavouring to popularise an instrument which, although it is the most important instrument used in astronomy for the determination of position, is at the same time one from which an immense amount of pleasure can be obtained by the merest tyro in science, whilst the great advantage of using such an instrument as this is, that no one can use it without rendering himself thoroughly familiar with some of the most important problems which lie at the root of any useful knowledge touching the stars, or the planet on which we dwell.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*

[*The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to insure the appearance even of communications containing interesting and novel facts.*]

Fossil Algæ

In a review of Saporta's work on "Fossil Algæ" in NATURE (vol. xxvii. p. 514) there are certain opinions brought forward which ought not to be passed by without some remarks. At first it should be stated that Saporta, while still insisting upon the vegetable nature of his so-called "algæ," does not only defend his views about those doubtful bodies which have been the objects of my criticisms, but also "defends" true algæ, concerning which I have never expressed any doubt. Such are, for example, the Florideæ represented on the first three plates in his work, and by "defending" them he puts me in a somewhat false position, at least in the eyes of the readers who have not studied my work.[1] The real fact is that I have only questioned—and still do so—the vegetable nature of almost all those objects which Schimper in Zittel's "Handbuch der Paleontologie" comprises under the head of "*Algæ incertæ sedis.*" There is consequently some exaggeration in Saporta's statement of my opinion.

Now it is quite clear that fossil trails of animals must occur in most cases in relief on the under sides of the slabs, the tracks in such cases being impressions in the soft sand or mud, which have since been filled by sediment. And it is also quite natural that the trails of animals should especially be found where there are alternating beds of sandstones and shales.

Now it is a fact that the Bilobites, as well as Eophyton, *always* occur in this way, projecting as convex bodies on the under sides

[1] A. G. Nathorst, "Om spår af några evertebrerade djur arbderas paleontologiska betydelse." With a French *résumé*, "Mémoire sur quelques traces d'animaux sans vertèbres et de leur portée paléontologique." (*Svenska Vetenskaps Akademiens Handlingar*, Bd. xviii., No. 7. Stockholm: Norsted och Söner, 1880.)

of the sandstones. Both Dr. Dawson and Dr. Linnarsson therefore long ago expressed the opinion that the Bilobites of Sweden and America must have been trails of some animals. In order to explain this mode of occurrence so that it might not appear as proof against the vegetable nature of the bodies, Saporta takes refuge in a somewhat curious manner of fossilisation described and illustrated by woodcuts in the review referred to. As I feel sure that every one who has made himself acquainted with true modes of fossilisation will immediately be aware that the process adopted by Saporta is indeed most improbable, it will be superfluous to dwell any longer on that question. But even granted that the plants *sometimes* should occur in this way—which statement I, however, think must be due to some confusion as to the real facts—such an occurrence could never be regarded but as a very rare exception to the general rule. And it therefore does not explain why the Bilobites should *only* occur in this, for true plants, exceptional way, (on the under surfaces of the slabs), *never* as true fossils embedded *in* the rock. This mode of occurrence harmonises, on the other hand, perfectly with the view that the Bilobites are trails of some animals, while it *cannot* be explained on the supposition that they are true organic bodies.

One arrives precisely at the same conclusions on studying their external structure, which possesses pretty great analogies as well with the trails of Limulus, long ago described by Dawson, as with those of other Crustaceans, described by myself. It is true that Saporta lays great stress on some superficial markings which are to be seen on some of the French specimens; but those who have studied not only the French Bilobites, but also those from Sweden or America, will soon be aware that the markings referred to are quite accidental. It is indeed surprising that Saporta, while adopting my views concerning Crossochorda, does not see that the Bilobites are somewhat analogous forms, though much larger. There is consequently no reason why they should be regarded as other than the trails of Crustaceans.

As for Eophyton, it is a pity that this should still be mentioned as possibly of organic origin. It occurs precisely as true trails on the under surface of the slabs; it is found in every system from the Cambrian to the present time, where it can still be studied on the seashores; all the different forms, under which it presents itself are also still to be seen there. Although it thus has been *proved* that it cannot be any organism, Saporta still adheres to the opposite opinion. Now, if he had read through my work, he would have learnt that I by experiment have demonstrated that Eophyton can not only be produced by drifting plants, but also by the tentacles of Medusæ or other soft bodies. Now there are casts of Medusæ associated with Cambrian Eophytons of Sweden, and their habits were probably—as I have elsewhere [1] tried to show—similar to those of the existing *Polyclonia frondosa*, which creeps on the mud by means of its tentacles, and it is therefore likely that the *Cambrian* Eophytons are of this origin.

It is further stated that "the Chondrites of the Flysch, strongly impregnated as they are with carbonaceous matter, are admitted on all hands to be Algæ, and the author asks how the same origin can be denied to casts of specifically identical Chondrites of the Cretaceous and so on to the Liassic forms." This argument is, however, a real "*petitio principii*," for it is so far from the actual state of things that the Chondrites of the Flysch are on all hands admitted to be Algæ, that many authors, and among them Dr. Th. Fuchs, of Vienna, whose excellent and exhaustive studies of the Flysch are everywhere known, hold a quite opposite opinion. And as for the supposed carbonaceous matter, it is not much better with this, as will be shown from a communication from Dr. Fuchs published in my work referred to: "The supposed carbonaceous nature of the Chondrites of the Flysch is in my opinion *a perfect mistake*. They are certainly very often quite black, but even in such cases they consist only of dark marl, *not* of coal."

Much more might be said on the fossil Algæ, but as I am about to combat the views held by Saporta more fully in a special work, I will here only add that I have found no statement whatever in his work referred to which would tend to alter my opinion, that almost all the "*Algæ incertæ sedis*" in Schimper-Zittel's "Handbuch der Paleontologie" are not vegetable fossils.

A. G. NATHORST

Stockholm, April 9

[1] A. G. Nathorst, "Om aftryck af Medusar i Sveriges Kambriska layer." (*Svenska Vetenskaps Akademiens Handlinger*, Bd. xix. No. 1, Stockholm: Norstedt och Söner, 1881.)

DR. NATHORST has certainly shown that many of the markings referred to Algæ by some authors might be tracks left by moving animals on a soft mud, but is there reason to suppose that there are conditions under which submarine surfaces of very soft mud with minute tracks have, or could ever have been preserved. On the other hand there is no question about seaweed having existed in Palæozoic and Mesozoic times, and either some of the markings in question are their prints, or no traces of them are preserved. Now it is an uncontroverted fact that even the most indestructible of all vegetable tissue, that of the Coniferæ, has been met with in the same condition of fossilisation, *i.e.* a projecting cast in sandstone on the under side of a slab, and without any internal trace of tissue or even of colouring due to carbon or iron, and Saporta has offered a satisfactory explanation of the origin of such casts. From the relative rarity with which terrestrial plants have been thus preserved, Nathorst almost derides Saporta's application of this explanation to fossil Algæ, yet it is by no means improbable that this may be their normal mode of preservation. The decay of dead olive-green seaweeds in water must be very rapid. The decomposition of some among them sets in almost immediately under water, and a colourless mucilaginous fluid is given off copiously. I have not watched the whole process of decay, but my impression is that the entire substance in some species would eventually pass away in a structureless glairy mass, and therefore that nothing but a hollow impression could ever be preserved. Casts of these would be more likely to be preserved in sand or mud than mere tracks, because the substance of the weed would occupy them, and prevent them from being immediately filled with the same quality of matrix as the surrounding rock, and until what would afterwards be a line of cleavage had been produced. So far therefore from its being exceptional for fossil seaweeds to appear as casts projecting from the under surface of the overlying mud, this is likely to be the normal condition in which fossil algæ are preserved. This is apart altogether from the question whether any of the Palæozoic markings are Algæ, for, these differ so considerably from any existing forms, that in the absence of internal structure it is quite unlikely that there will be any general agreement respecting them. These observations do not apply to the Rhodospermeæ, which scarcely enter into the question. Some simple experiments on the decay of seaweeds in fine sand under water, which any one at the seaside could make, would help to throw light on the subject.

J. S. GARDNER

The Weather and Sunspots

IN NATURE (vol. xxvii. p. 551) Mr. Williams ascribes the great cold of March, 1883, at the Riviera, to the absence of sunspots. There is the less reason for ascribing this cold to sunspots, as till now much more evidence goes the other way. And may it not be contended that this evidence is in favour of warm weather, with minimum sunspots in the tropics or in summer alone. The months of November to March, 1877–78, especially February and March, were so warm over an extensive area, especially in the interior of North America and Western Siberia, that the mean temperatures were nearly without precedent, while in no extensive country of the world the temperature was much below the average.

I give some data for March, 1874 (a season with a considerable number of sunspots), at Suchum-Kale, on the east coast of the Black Sea, a place in the same latitude as Cannes, and similarly situated in respect to sea and mountains; it is sheltered from cold winds, and much warmer than the surrounding country.

The observations in Russia being made at 7 a.m. and 1 and 9 p.m., and no minimum-thermometer used, the minima cannot be strictly compared.

The mean temperatures for a long average at Nizza (which are about the same as at Cannes) are January 47°·1, March 51°·8; at Suchum-Kale, January 43°·0, March 47°·8, being at both about 4° colder. Taking the mean of minimum and maximum as the daily mean at Cannes, and that of 7 a.m. and 1 and 9 p.m. as the daily mean at Suchum, we have: Coldest days of March, 1883, at Cannes, 10th, mean 35°·5, or 16°·3 below average; 11th, 34°·5, or 17°·3 below average; lowest minimum on the 11th, 24°·1, or 27°·7 below monthly mean temperature. Coldest days of March, 1874, at Suchum, 3rd, 19°·9, or 27°·9 below average; 4th, 20°·5, 27°·3 below average; 5th, 20°·8, 27°·0 below average. The lowest temperature at 7 a.m. was, on the 6th, 16°·4, or 31°·4 *below average monthly temperature*. Thus it is seen that at

Suchum, in the same latitude and in a very similar situation as Cannes, in March, 1874, a year with a considerable number of sunspots, there were three days which were more than 27° colder than the average, while in March, 1883, with little or no sunspots, the coldest days mentioned by Mr. Williams at Cannes was only 17°·3 colder than the average.

I want only to show by this example that if it is wished to prove anything as to the varying intensity of the sun's rays, a large number of observations in distant countries should be given, especially in middle latitudes, the work of Dové having well proved that there is always a compensation to a certain extent between cold and warm areas, and a very great number of these deviations being certainly due to causes which have nothing to do with anything beyond the earth's atmosphere.

St. Petersburg, April 17 A. WOEIKOF

Sheet Lightning

LOOKING to the south and south-east from the Bel Alp, the play of silent lightning among the clouds and mountains is sometimes very wonderful. It may be seen palpitating for hours, with a barely appreciable interval between the thrills. Most of those who see it regard it as lightning without thunder—*Blitz ohne Donner*, *Wetterleuchten*, I have heard it named by German visitors.

The Monte Generoso, overlooking the Lake of Lugano, is about fifty miles from the Bel Alp as the crow flies. The two points are connected by telegraph; and frequently when the *Wetterleuchten*, as seen from the Bel Alp, was in full play I have telegraphed to the proprietor of the Monte Generoso Hotel, and learnt in every instance that our silent lightning coexisted in time with a thunderstorm more or less "terrific" in Upper Italy. JOHN TYNDALL

May 12

I AM glad to find that M. Antoine d'Abbadie's remarks confirm in the main those which I have made on the above subject in NATURE (vol. xxviii. p. 4), especially as to the occurrence of lightning at a great altitude as observed in low latitudes.

In stating that he has frequently observed "thunder without lightning, and lightning without thunder," does M. d'Abbadie mean that, like every one else, he has observed thunder without observing lightning, and lightning without observing thunder? Or have we here a living advocate not only of the dumb lightning, but of the dark (lightningless) thunder?

The thin and local fogs which are not uncommon in thundery weather readily transmit the illumination of a distant flash of lightning. It seems highly probable that in such cases the lightning may be occasionally supposed to be an electric discharge occurring in the fog itself, just as a flickering aurora seen above thin clouds has often been supposed to have its habitat in the clouds themselves.

The suggestion of M. d'Abbadie is a fair one, and I for my part shall be glad to undertake observations of "sheet lightning" this summer in conjunction with any one resident about forty miles from this place, the observers interchanging reports by the earliest post after the hour of observation.

Hydrogen Whistles

IN his interesting communication on the above topic (NATURE, vol. xxvii. p. 491) Dr. Francis Galton has inadvertently fallen into a mistake which quite seriously affects the numerical deductions which follow. He erroneously assumes that "the number of vibrations per second caused by whistles is inversely proportional to the specific gravity of the gas that is blown through them."

It is well known that the number of vibrations is inversely proportional to the *square root* of the density or specific gravity of the gas. Hence for hydrogen, as compared with air, the number of vibrations per second produced by a given whistle would be increased only about 3·6-fold instead of 13-fold, as he estimates it. Similarly the number of vibrations by the use of hydrogen in the little whistle when set at 0·14 inches would be only about 86,533, instead of 312,000. JOHN LE CONTE

Berkeley, Cal., April 12

[THE objection of your correspondent is valid. I am informed independently and by high authority that the velocity of sound in hydrogen must be considered as barely fourfold greater than in air, the number of vibrations per second emitted by a hydrogen whistle being increased in the same proportion.

In making my earlier estimate I had been misled by an erroneous statement in a work that is still of much general credit and authority, to which I referred for ascertaining the velocity of sound in different gases, as it happened to be the book then nearest at hand, and as I have no special knowledge of the subject. It was the first edition of the *Penny Cyclopædia*, where in the article "Acoustics," p. 95, I lit upon the following passage, which professed to give the precise information I wanted:—"Thus air being about thirteen times as heavy as hydrogen, the velocity of propagation in the latter is about thirteen times that in the former." I need not take up your space by quoting the paragraphs before and after this, which emphasise and corroborate the statement and make it clear that it was no slip of the pen. Possessors of this Cyclopædia (I know nothing of subsequent editions) would do well to look out the passage and put a note of warning by the side of it.

The fourfold gain, or nearly so, of the hydrogen whistle is not to be despised. It is sufficient to establish its rank as the emitter of the largest number of aërial vibrations per second of any instrument yet contrived. My little whistle, of about 1 mm. bore, requires a very small supply of air, a bag that I fill with a single expiration containing enough to keep it in continuous sound for many minutes. As yet I have not got a portable holder for pure, dry hydrogen, but a well-known chemist is kindly making an experiment of one for me.

FRANCIS GALTON]

The Pillar of Light

I HAVE frequently observed this phenomenon. The first time I saw it was on April 8, 1852, when I saw it here at sunset, and on April 11 I saw it at sunrise when I was in the Irish Channel, near to Port Patrick, where I was laying a submarine cable.

In the *Monthly Notices* of the R.A.S. vol. xii. p. 185, there are several notices of its having been seen at that time in various places. I saw it last on April 6 this year, when it had the same appearance as previously, which is well represented by Mr. Symond's drawing on p. 7, except that the lower part is too bright, and it looks more correct when shaded with a pencil. The pillar is always perpendicular to the horizon and to the sun's position. I saw the zodiacal light several times in February, extending as far as the Pleiades, and at an angle of about 45°. I think it is highly probable that the pillar of light is caused by reflection from ice crystals, as we had very cold weather early in April, and have still. These atmospheric phenomena are often best seen reflected from a plate glass window.

Gateshead, May 9 R. S. NEWALL

Remarkable Lunar Phenomenon observed at Weston-super-Mare, August 21, 1861

AT about 8.30 p.m. a band of silvery light appeared proceeding from the lower margin of the moon, in a line perpendicular to the horizon. The width of this band was equal to the exact apparent diameter of the moon's disk. Slowly the band lengthened, until its upper portion reached beyond the moon to the extent of about two diameters, while the lower limb extended itself to about the length of four diameters, where its foot rested apparently on a light fleecy cloud. In a few minutes a similar band traversed the other at right angles, forming a perfect Latin cross, the brilliant face of the moon occupying the place of intersection. The arms of the cross were respectively about two diameters of the moon's face. The portion of the sky in which this occurred was clear, but clouds were slowly drifting from the west, and in ten minutes began to obscure this beautiful and unusual phenomenon.

The only record of any similar phenomenon which I can meet with is to be found in Lowe's treatise on atmospheric phenomena, wherein two instances are described. The observer of one was Dr. Armstrong, and the appearance was seen by him at South Lambeth on February 25, 1842. The other observer was Mr. Lowe himself, who was at Derby railway station when the phenomenon occurred. In both these instances, however, the crossbeam was absent. Although no hypothesis has been suggested to account for this appearance, it may be interesting to note that in the case recorded by Mr. Lowe, the very

hour of its occurrence is identical with that of the appearance of the phenomenon seen by me, and the day of the month so closely approximates as to be only one day later. That which Dr. Armstrong saw in 1842 was at the time of the full moon in February.

C. POOLEY

Curious Habit of a Brazilian Moth

AT the last meeting of the Literary and Philosophical Society of Liverpool (April 30) I read the following note on a remarkable habit of a Brazilian moth; and as it is a habit that has perhaps not been observed before, it may be of sufficient interest for insertion in NATURE.

The moth (of which I inclose a sketch) is a species of Panthera (*P. Apardalaria*).

When rambling about the rocky beds of small streams on the Serra da Contareira, near San Paulo, I have often been struck by the great numbers of yellow and black moths that flew up from the water as I disturbed them by my presence. On careful examination I found that these moths were resting upon the wet stones, in many cases even with a film of water flowing over the spot on which they had settled, and were all engaged in sucking up the water through the proboscis (I can hardly call it drinking, for no imaginable thirst could account for the enormous amount of water sucked up), and this water was passing through the moths, minute drops forming on the tip of the abdomen, and falling off as formed. I timed several specimens, and found that the average rate was fifty drops per minute. I have observed the same individual remain in the same position with the action going on unceasingly for three hours; and in all probability it had been there some time before I observed it, and remained after I went away. But even in this length of time the quantity of water passing through the moth was enormous in proportion to its size. The drops I did not actually measure, but they are probably between 1 and 2 millimetres in diameter. Taking them to be 1·5 millimetres in diameter, the total amount of water in the three hours was 15·84 cubic centimetres, or almost exactly a cubic inch. This quantity is equal to about 200 times the volume of the body of the moth!

The tibiæ of the hindlegs are very thick and are armed with long hairs, that by their capillary action prevent the moth being immersed in the water. I have often seen one of them knocked down by a little spurt of water splashing over the stone on which it was standing, and it recovered itself immediately without being wetted in the least.

Upon my return to Brazil I shall try to measure exactly the amount of water passing through one of these moths. And it would be most interesting to find out what is the object of this excessive drinking. Can it be that the moth extracts nourishment from minute particles of organic matter contained in the water?

I may remark that the water of the streams where I have observed the moth is very clear and pure.

Acrefield, Woolton, Liverpool, May 5

Leaves and their Environment

I TAKE the following from an experiment which I made two years ago. I think it throws some light on the point under discussion:—

On May 8 six young pea plants, similar in size, &c., were transplanted from the garden into three large flowerpots, a pair in each, and were covered with bell glasses. On next day an apparatus for generating a constant stream of carbonic acid gas was connected to No. 1 bell glass. No. 2 was left normal. No. 3 inclosed a small disk of caustic potash solution. They all had as nearly as possible the same amount of sunlight, and the same measured quantity of water was given to each.

Taking the notes referring to the leaves only I find on May 21: "No. 1, vigorous large leaves. No. 2, much smaller leaves. No. 3, leaves smaller than No. 2, with edges serrated as if the veins were growing on, but could not find food for fleshy part of leaf—really a starved plant."

On May 27 the plants were taken up and washed, when No. 1 weighed 148 grains; No. 2, 115·5 grains; and No. 3, 87 grains. After drying, the weights of Nos. 1 and 3 were as 19 to 13. The longest leaf on No. 1 measured $1\frac{5}{8}$ in., and on No. 3 $1\frac{1}{8}$ in.

J. BROWN

Belfast, May 3

Foam Balls

IN NATURE, vol. xxvii. p. 531, there is a mention by Mr. J. Rand Capron of foam balls. These are common on the coast of the Northern United States, especially of a cold dry day, when, if there be much wind, these huge foam balls, which may reach a diameter of two feet or more, are rolled up the beach. Their weight soon changes their form, so that at last they present the appearance of long white rolls of sparkling foam. This singular appearance was first described in verse, so far as I know, by Dr. S. Weir Mitchell, of Philadelphia. The verse, as I recall it—I quote from memory—is this:—

> "And wilder yet when of a winter day
> The cold dry norther rolls athwart the beach
> The gleaming foam balls into serpents white,
> And all the sand is starred with rainbow light."

Philadelphia, U.S. AN AMERICAN SUBSCRIBER

ANTHROPOLOGY[1]

II.

IN considering the claims of anthropology as a practical means of understanding ourselves, our own thoughts and ways, we have to form an opinion how the ideas and arts of any people are to be accounted for as developed from preceding stages. To work out the lines along which the process of organisation has actually moved, is a task needing caution and reserve. A tribe may have some art which plainly shows progress from a ruder state of things, and yet it may be wrong to suppose this development to have taken place among themselves—it may be an item of higher culture that they have learnt from sight of a more advanced nation. Our own history shows to how small an extent we have been the developers of our own arts and sciences, how largely we have embodied the culture of other nations. It is essential in studying even savage and barbaric culture, to allow for borrowing, so as to clear the lines of real development. When the savage comes into contact with the civilised man, he does not see his way to copy all the high contrivances of this mysterious higher being, but where he thinks he can imitate, he is apt to try, and sometimes succeeds, though oftener fails. After a time of friendly intercourse, the wild man generally learns such substantial secrets of culture as he is in a position to assimilate. Ethnologists have been inclined to look on the wandering Esquimaux of the polar regions as "nature-men," and perhaps no harm has arisen from reasoning on them as such, for they are in many ways fair representatives of the rude nomad hunter and fisher. But I suspect that in some respects they do not show the mere result of the primitive savage working out by slow degrees a somewhat higher culture. Looking at them not as they are now, Europeanised under missionary training, but as they were when Egede and Cranz went out to them from Denmark in the eighteenth century, it seems that their way of life even then had some incidents above the savage level. Their clothing was artistically contrived to resist the intense cold. Its material is sometimes strange to our notions; an undershirt of birds' skins with the feathers inside requires an effort to realise even in our bleakest season. But a leather tunic with sleeves and a hood to pull over the head, a pair of sealskin breeches with leather stockings and boots, form a defence against the cold, at once like that familiar to Europeans, and unlike any unquestionable savage costume, such as the furs which in the Antarctic regions the shivering Fuegians throw over their shoulders. Moreover, all across the polar coast region of the Esquimaux their houses of earth or moulded snow, with compartments like ship-cabins, are warmed and lighted with blubber, burnt in lamps shaped out of potstone with moss to serve as wick, and over these are hung the potstone kettles for their slight cookery. Now,

[1] Two lectures on "Anthropology," delivered on February 15 and 21 at the University Museum, Oxford, by E. B. Tylor, D.C.L., F.R.S. Continued from p. 11.

the kettle carved out of potstone (lapis ollaris) is ancient in Scandinavia, and the plain open dish lamp occurs widely in Northern Europe (it lingered till lately in the Scotch *crusie*). But the lowest races know nothing of so cultured an invention as a lamp. It is of course within the wide bounds of possibility that under the stress of a climate so cold for loose-clad, half-naked men, and where the scanty supply of wood drifted to the shore was too precious for fuel, the Esquimaux, driven by the warlike American Indian tribes of Algonquins and Athabascas, may have discovered how to improve their clothing, and to warm and feed themselves by the aid of lamps, so that they could hold their own against the rigour of polar nature. But if so, how curious that they should have done this by inventing just what the Norsemen could have taught them. Independent Greenland invention, if possible, is hardly probable, and I think a strong case may be made for an easier explanation. We know that the ancestors of the Esquimaux had been in contact with Scandinavians since before our Norman Conquest, when in 1004 the small, sallow, broad-cheeked Skrällings in their skin canoes slew Thorvald with their spears thrown with throwing-sticks, and he was buried with a cross at head and feet at Crossness, which may have been about where long afterwards the Puritan emigrants landed from the *Mayflower*. It seems clear that the Esquimaux had to go north from these delightful regions of New England, but they lived for ages within reach of the Norse settlers in Greenland, whose last survivors in the fourteenth century are thought even to have merged their race in some tribe of the despised Skrällings. Thus it is not surprising that the Scandinavians returning to Greenland after four hundred years more should have found the Esquimaux shaping their skins and furs into semi-European garb, and by the aid of these and the stone lamps and kettles maintaining a polar existence which, without these, would have been difficult indeed. Even that curious Scandinavian institution, the scurrilous nith-songs with which the Norse champions drove one another wild with fury, so that they had to be prohibited by law under heavy penalties, had become a regular Esquimaux custom, and Rink calls them simply *nid-vise*, just as he would have called them among his own Danish forefathers. His first specimen is a Greenland song sung at festive winter gatherings, made to ridicule one Kukouk, who was a poor hunter and fisher, but loved to make friends with the white men; it begins—

> "Wretched little Kukouk
> He takes care of himself;" &c.

If this view of a Scandinavian element in the culture of the Greenlanders is sound, we have the curious spectacle of modern Danes going to civilise the wild men and describing their manners and customs as those of savages, without a thought that some of the most curious of them were relics of forgotten life of their own old Norse-land.

That families can go down in the world is only too well known, nay, that whole tribes and nations can in evil days fall off from their old prosperity, intelligence, and virtue. The question asked by the anthropologist is whether a civilised race can sink to the barbaric level, and thence to the lowest or savage level. The answer is as yet in a confused state, but certain elements of truth may already be got at. It appears at any rate that when civilised men take to a wild life, and mix with the people of the wilderness, they may give rise to a race in whom knowledge and comfort and morality are lowered from the ancestral level. This is the familiar case of the Gauchos of the Pampas, Spaniards in language and partly in race, but leading a life which to the soldiers of Pizarro would have seemed gross and brutal. In the forests of Ceylon there still roam families of wild men, the so-called Veddas or hunters who, as names of places show, once lived widely over the country till dispossessed by the invading nations from India. The wildest Veddas are to be found in the park-like hunting-grounds of Nilgala, and in "the land of Bintan, all covered with mighty woods and filled with abundance of deer," as Robert Knox described it two centuries ago. These wild shy people, of stature averaging under five feet, and in skin duskier than the Singhalese around them, with tiny heads covered with a mass of shaggy hair, and showing in their dull and melancholy faces that uniformity of feature and expression so characteristic of low grades of culture, may seem at first sight to lead a life comparable with that of the forest savages of Brazil or New Guinea. Yet their language is a Singhalese dialect; they are in fact the one known race who may be called savages, and yet speak a language of our own Aryan stock. The following is one of their charms, intended to subdue an elephant in the forest, whom it describes in terms which show a curious transition between the charm and the riddle; indeed, every one who remembers our own nursery riddle about the cow will be struck with its close resemblance to the Vedda charm:—

> "Ichchata vallay
> Pachchata vallay
> Déli devallay
> Situ appá situ."

> "In front a tail,
> Behind a tail,
> On the two sides two tails,
> Stay, beast, stay!"

This is almost Sanskrit, and it is obvious that with so distinctly Aryan language there must needs come some strain of Aryan blood, for it is almost outside the possibilities of social life that a tribe should adopt a language, without such intermarriage with those who speak it that thenceforth the people will in part have ancestry corresponding to the new tongue. The Singhalese indeed hold the Veddas to be of Aryan descent, and in the Mahawanso they stand as offspring of no less an Aryan ancestor than King Vijayo, who married the native princess Kuvéni, and by her means conquered the Island of Ceylon; afterwards, when he ungratefully divorced her and took a daughter of King Pandavo of Madura, the native queen wandered away, and her children married in-and-in, as continued till lately to be Vedda custom. This, says the poem, was the origin of these Pulindá or barbarians; and thus it is that they still claim royal descent, and look down on the Singhalese. Combining the evidence of the Vedda skulls and features with that of their language, we may so far agree with poetic legend as to consider them really outcasts of mixed Aryan and Dravidian or indigenous race. If so, it must be granted that descendants of the Aryan stock, "heirs of all the ages in the foremost files of time," may be found among tiny, shy, wild men of the woods, with sad dull features peering out of their matted locks, who dwell in huts of boughs when they cannot get the preferred shelter of a cave, who live on venison and wild honey and fish drugged by putting poisonous fruit in the pools, and who in their intercourse with the more cultured Singhalese bring themselves into contempt by their simple truthfulness, that utter incapability of cheating and lying which is as characteristic of the savage state as it is rare at higher levels of culture. Truly the condition of these poor relations of ours is of interest. But they are not Aryans on their way upward from primitive rudeness. Their kinsfolk actually till patches of ground and are a settled if a rude people, and these wildest Veddas are evidently a few dwindling clans of outcasts sunk from a higher stage. There is not among them any evidence that they have been in the Stone Age; a story is told of them like our own legend of Wayland Smith's cave, that in old times when they wanted arrows they would carry loads of meat to the smith's shop in the night, and hang it there with a leaf cut to the pattern of the arrow-heads they expected him to leave out in exchange; at any rate it is certain that they have always

had iron by barter from more civilised neighbours, and their occupations, especially the taking of wild honey, are such as belong to the Singhalese.

In the presence of such examples as these, anthropologists admit that civilisation has always had its ups and downs. A nation may themselves develop some thought or art, or borrow it from abroad, and then ages afterwards lose this knowledge or skill because they have no longer the power or leisure to keep it up. It is only after taking such cautionary examples of the migration and degeneration of culture, that it becomes safe to trace the lines along which civilisation has developed in the world.

"When will hearing be like seeing?" says the Persian proverb. Words of description will never give the grasp that the mind takes through actual sight and handling of objects, and this is why in fixing and forming ideas of civilisation, a museum is so necessary. One understands the function of such a museum the better for knowing how the remarkable collection formed by General Pitt-Rivers came into existence. About 1851 its collector, then Colonel Lane Fox, was serving on a military subcommittee to examine improvements in small arms. In those days the British army was still armed (except special riflemen) with the old smooth-bore percussion musket, the well-known "Brown Bess." The improved weapons of Continental armies had brought on the question of reform, but the task of this committee of juniors to press changes on the heads of the service was not an easy one, even when the Duke of Wellington, at last convinced by actual trial at the butts, decreed that he would have every man in the army armed with a rifle musket. Colonel Fox was no mere theorist, but a practical man who knew what to do and how to do it, and his place in the history of the destructive machinery of war is marked by his having been the originator and first instructor of the School of Musketry at Hythe. While engaged in this work of improving weapons, his experience led his thoughts into a new channel. It was forced upon him that stubbornly fixed military habit could not accept progress by leaps and bounds, only by small partial changes, an alteration of the form of the bullet here, then a slight change in the grooving of the barrel, and so on, till a succession of these small changes gradually transformed a weapon of low organisation into a higher one, while the disappearance of the intermediate steps as they were superseded left apparent gaps in the stages of the invention, gaps which those who had followed its actual course knew to have been really filled up by a series of intermediate stages. These stages Colonel Lane Fox collected and arranged in their actual order of development, and thereupon there grew up in his mind the idea that such had been the general course of development of arts among mankind. He set himself to collect weapons and other implements till the walls of his house were covered from cellar to attic with series of spears, boomerangs, bows, and other instruments so grouped as to show the probable history of their development. After a while this expanded far beyond the limits of a private collection, and grew into his Museum. There the student may observe in the actual specimens the transitions by which the parrying-stick used in Australia and elsewhere to ward off spears must have passed into the shield. It is remarkable that one of the forms of shield which lasted on latest into modern times had not passed into a mere screen, but was still, so to speak, fenced with: this was the target carried by the Highland regiments in the Low Countries in 1747. In this museum, again, are shown the series of changes through which the rudest protection of the warrior by the hides of animals led on to elaborate suits of plate and chain armour. The principles which are true of the development of weapons are not less applicable to peaceful instruments, whose history is illustrated in this collection. It is seen how (as was pointed out by the late Carl Engel) the primitive stringed instrument was the hunter's bow, furnished afterwards with a gourd to strengthen the tone by resonance, till at last the hollow resonator came to be formed in the body of the instrument, as in the harp or violin. Thus the hookah or nargileh still keeps something of the shape of the coco-nut shell from which it was originally made and is still called after (Persian, *nárjíl* = coco-nut). But why describe more of these lines of development when the very point of the argument is that verbal description fails to do them justice, and that really to understand them they ought to be followed in the series of actual specimens. All who have been initiated into the principle of development or modified sequence know how admirable a training the study of these tangible things is for the study of other branches of human history, where intermediate stages have more often disappeared, and therefore trained skill and judgment are the more needed to guide the imagination of the student in reconstructing the course along which art and science, morals and government, have moved since they began, and will continue to move in the future.

It is convenient in illustrating intellectual development to choose a branch where every one, so to speak, carries his specimens about with him. Some eighteen years since I made an attempt to describe and analyse the gesture-language, in order to show the consistency of principle with which men debarred from spoken language, whether deaf-mutes or men unacquainted with one another's languages, contrive to utter their own thoughts and understand the thoughts of others through expressive gestures. In these gestures we have a direct and universal outcome of the human mind, a system by which a deaf and dumb scholar from an English asylum can hold converse at first sight with Laplanders or Iroquois or Chinese. They understand each other because they use signs for the most part self-expressive, and conveying their own meaning to those who never saw them before. Now any idea can be thus conveyed by self-expressive signs, not in one way alone but many. A hunter of the prairie, for example, has to express the idea "horse": this he can do by various signs, as by the hand so held as to imitate a horse's head, or by the act of straddling a pair of forked fingers across the edge of the other hand, or by the imitated motion of the gallop; different as these signs are, each tells its own tale. When, however, people have been long used to converse together in gestures, they are apt to cut them down into abbreviated forms which do not show their meaning at first sight, and might even seem to outsiders to be artificial. Thus, a white man, seeing a Cheyenne Indian hold his bent arm forward with the hand closed knuckles upwards, was puzzled as to what this might mean; the Indian, seeing his look of perplexity, took a stick, and bending his head and back, completed the picture into that of a bent old man leaning on a staff, thus showing that the sign meant "old man." Traditional signs may even go on after their reason has passed away, as the sign for "stone," made by hammering with the closed fist on the other hand, a gesture dating from the Stone Age, in which the Indians lived within a few generations, when their only hammer was a stone. These two examples are taken from the recent careful collection of North American gesture-signs by Col. Mallery, published by the Smithsonian Institution. The labour and expense which anthropologists in the United States are now bestowing on the study of the indigenous tribes contrasts, I am sorry to say, with the indifference shown to such observations in Canada, where the habits of yet more interesting native tribes are allowed to die out without even a record. But to return to the gesture-language. This passage of self-expressive signs into what seem arbitrary signs throws strong light on the principles of spoken language, where we find a few self-expressive sounds, such as interjections and names of animals imitated from their cries, while the great majority of words are not even traceable back to the self-expressive

stage from which the analogy of gesture-language leads us to suppose that they originally sprang. Moreover, the sequence or collocation of gesture-signs conforms to fixed rules, which display the action of the thinking mind. The subject must precede the attribute: for instance, such a sequence as a "heavy stick" would have no sense to the sign-maker, who necessarily introduces the stick before he can clothe it with an attribute. Phrases, so to speak, out of an American gesture-story illustrate the gesture-syntax. When the finger-tips of the two hands are brought together to show a hut or wigwam, then pointing to one's own breast does the work of the pronoun, "hut-mine." The sequence "buffalo-one-shot-killed" starts with the idea of buffalo, adds that there was one, and then the sign-maker, having placed the idea of that one buffalo before his interlocutor, can imitatively shoot at it, and it falls dead. He can even imply the idea of causation in the sharp following of the shot by the animal's fall, which makes one the instantaneous consequence of the other. In spoken language the theory of syntax or combining-order is a subject of great complexity and difficulty. Of the few philologists who have attempted it, mention may be made of Steinthal, von der Gabelentz, and Max Müller, whose early dissertation is published as an appendix to Bunsen's "Philosophy of Universal History." But while the age-long shifting history of speech has brought the order of sequence of its elements into an entanglement hardly possible to unravel, we have still before us the first clue in the sequence by which man has arranged his gestures, and will do so anew when he is put to pantomime as a means of converse. Thus the philologist, engaged in studying the formation and combination of speech-sounds or words, may have from the anthropologist the natural rules framed by the human mind dealing in the simplest of known ways with the problem how to express thought.

Scarcely less light is thrown on the working of the human mind by the history of that special development of error which since the remotest ages has taken the form of magic. Of late certain events in France have revived popular interest in that curious old-fashioned instrument, the divining-rod, and as I happened to be staying at a friend's house in the Mendip district, where it is still used by well-sinkers and miners, at my request a regular practitioner was sent for. I show the instrument—a forked hazel twig, which is held loosely by its outward-bent ends in the closed upturned hands, so that it can rise or fall easily. On approaching a spring, vein of ore, &c., the rod dips toward it, but when replaced horizontally and passing over the place, it rises toward the bearer's face. That the spring or other object sought has really no effect on the instrument, but that its dipping has to do with the seeker, is sufficiently shown by its being considered to act with the most dissimilar objects—a spring of water, a vein of ore, a piece of metal, a dead body—which have, however, this in common, that they are what the "dowser" is in search of. It does not appear that he fraudulently moves the rod, but my sensations led me to agree with Chevreul that the slight movements of the hands are unconsciously guided to accumulate into impulses sufficient to cause the twig to dip or rise. I noticed that when I could allow my attention to stray, the rod would from time to time move in my hands in a way so lifelike that an uneducated person might well suppose the movement to be spontaneous. It is hardly necessary to say that the rod always moves where the bearer's mind suggests an object. In the present case the special business of the dowser was to find springs of water, and his difficulty was to distinguish between the mere *top springs*, which though acting on the rod were of course practically worthless, and the valuable *main springs* which would repay the sinking of a well. In the trial an incident occurred which threw light on the nature of the whole operation. The rod when brought over my watch, dipped strongly, and the dowser looking up at me with innocent archness said: "You see, sir, it's just over the *mainspring* of your watch." The remark showed how his mind was so simply controlled by association of ideas, that he expected the same action from a *main spring* of water and of a watch, their likeness of name quite overriding their unlikeness of nature. Nothing could have better shown at once the man's sincerity and the purely ideal character of his craft, nor does one often meet with a more perfect illustration of the state of mind where magic has its origin in delusive analogy, whether of things or of their names. Magic has often passed as mystery, but to the anthropologist few arts are less mysterious; he reads by childishly simple association of ideas the open secret of half the magical rules which prevail in savage and barbaric life, and even last on into the midst of civilisation. In the wild north-west of Ireland I learnt not long since the use of the "worm-knot" for curing ailments of cattle; it is a bit of cord in which a peculiar slip-knot is made, and if this knot when pulled over the creature's back comes away clear (as shown), the disease will come away too. On the same principle, the purpose of the pig's heart stuck full of thorns and bricked up in an old chimney (produced) was sympathetically to pierce with pain and shrivel with disease some hated person, probably a reputed witch suspected of "overlooking." It is a curious exercise to read from this point of view the precepts of the modern astrologer, which still show their quasi-reasons, futile but quite intelligible. Suppose one's self seeking for lost property, the significator of the thing missing will be the moon, apparently because herself so often lost and found again. According to her position, east or west, the object must be looked for; if the Moon is in a human sign, as the Twins, it will be in a human habitation, but the sign of the Bull indicates its being in a cow-house. Even the thief's clothes are denoted by the governing planets; under Saturn he will be found in a black suit, or if Mars is in it, his presence will be shown by some red article, perhaps a neck-handkerchief. Folly as this is, it at any rate shows the working of uneducated men's minds, where the argument from analogy appears in its early crude state, not yet cleared by observation, but still on its way to become, under proper checks and reservations, the explorer of the universe and the guide to science.

This is by no means the only example of a delusive theory being, when honestly worked out, productive of scientific truth. In times when the study of races for mere knowledge sake had little hold on scholars' minds, anthropology was much indebted to the fancy that any people whose presence in an outlying region seemed hard to account for must be the "lost tribes of Israel." One nation answered the conditions of this theory about as well as another: the remnants of the ten tribes were found marauding in the Afghan passes, wandering with the reindeer in Lapland, chasing buffaloes on the American prairies, or slaughtering human victims on the teocallis of Mexico. The manners and customs of these countries being studied, showed distinct analogies with Jewish customs, as indeed they would have with German or Chinese, or any other. Enthusiasts such as Rudbeck, or Garcia, or Adair, of course did not see this, but the practical result was that, especially in North and South America, evidence of great value in the history of civilisation was recorded which would have perished had it not been thus caught before it was swept away by European influence. This is a good instance of its being better to have a bad hypothesis than none at all. The ten tribes delusion has now, however, sunk to a lower level than when Lord Kingsborough spent his fortune in publishing the Mexican pictures and chronicles. But in spite of all the new real knowledge as to races, it has even in this country more

votaries than ever. On opening, the other day, a book of the curious "Anglo-Israelite" sect, I met with the following passage, written in evident seriousness by a seeker after proofs that the British nation are the Lost Tribes of Israel:—"I am even now acquainted with many words in current use in some parts of the West of England that were in common use by Israel of old, and that I have not found in use in any other country—such as goad, gourd, barm, leaven, comrade, lattice, chambering, flay, score, gallon, cruse, lintel, latchet, girdle, pitcher, platter, glean, &c., &c." It takes a little thought to understand the full depth of ignorance of a man who, finding these words in the English Bible, thought they were used by the ancient Israelites. Why I ask you to notice it is that the author of the volume it is printed in says that 100,000 copies of his work have been sold; there is, indeed, no doubt but that this abject nonsense has a far larger circulation than all the rational ethnology published in England. It opens a window by which we can see into the state of education of its readers, who mainly belong to the lower middle class, and whose thousands of schools are as yet unvisited by the University Delegates on the one hand or the Education Department on the other. Even our Public Elementary education, good as it is in many respects, passes some questionable anthropology. Happening to look a few days ago at a Third Standard book on English History, I was surprised to find a picture of a South Sea Islander, tattooed all over, standing to represent the condition of the ancient Britons, who are described as savages. Now this is hardly an appropriate designation for a pastoral and agricultural people, who had a gold coinage, and whose war-chariots even the Roman legionaries found troublesome to deal with.

Having now attempted to support the claims of the problems of human nature to fuller recognition in our system of advanced education, it may be well to observe by way of caution that anthropology, while contributing materials to other sciences, does not dictate the conclusions which each science is to draw from them. It has not a rule of morals, a system of politics, or a doctrine of religion to teach, only a series of facts showing the stages through which each of these has been developed, and with these the counsel that the anthropological way of studying human conduct is to trace its principles along the historical line of their change and progress. Anthropology, though acknowledging degeneration as an important factor in human life, gives no encouragement to pessimist theories of society. The clinging to life by savage and civilised alike is a measure of their judgment that with all its ills it is a substantial good, to be valued and defended. That the tendency of mankind is toward industrial progress need not be proved, for it is not denied. That moral progress is on the same footing rests on the main fact that man obtains the happiness he seeks, not only through his own sensations but by sympathy with the enjoyments of others; now beings whose interests are thus consonant with the prosperity of those around them are plainly on the road to good rather than evil. At the same time facts constantly presenting themselves in anthropology guard the student from a prejudiced optimism. He has the picture constantly before him of low-cultured but kindly and truthful tribes of favoured climates, into whose midst the march of civilisation is bringing the beginnings of trade and wealth, and with them temptations to selfishness and dishonesty. At every step in the advance towards prosperity he sees, accompanying the growth of knowledge and the raising of the social standard, a series of concomitant evils, the break-up of the old stage, the failure to assimilate the new. Often a dispiriting lesson, this is yet of the highest practical value, for it elucidates what the statesman should be ever striving to learn, how, in the remodelling of institutions, to gain the utmost advantage while minimising the accompanying loss.

To conclude: my explanation of the unsymmetrical way in which I have here put forward the cause of anthropology must be that the necessity of the case compelled me to a certain scrappiness of treatment. For presenting my subject thus in shreds and patches I am tempted to apologise in that well-worn lecturer's jest, the story of the man who had a house to sell and carried about a brick as a specimen. Perhaps, however, there may be more of a moral in this story than is commonly supposed. I cannot help fancying that the flippant Greek who first told it had actually seen something of the kind done in sober earnest. He may have watched some grave Roman going down to the prætor's court carrying a tile in his hands, which in the lawsuit was to be the legal symbol of the house itself, just as a farm would be represented by a sod of its turf, or as one of our Teutonic forefathers, living in a wooden house, would transfer it by handing over a chip from the doorpost. This indeed is the very position in which I find myself placed in undertaking to treat of anthropology in two lectures. Because the whole structure is too extensive and too massive to bring into court, I have been obliged to symbolise it by fragments taken here and there, and can only ask that these be accepted as symbols, placing the edifice they represent under the guardianship of the University of Oxford.

THE ARCTIC METEOROLOGICAL STATION ON THE LENA

THE last number of the *Izvestia* of the East-Siberian branch of the Russian Geographical Society gives further news of the Lena Arctic Meteorological Station, dated October 24, 1882. This news was brought by the American officers, Messrs. Garber and Schütze, who left the station on October 25, and reached Yakutsk on November 29. Mr. Schütze made a sketch of the station, which appeared in the *Izvestia*, and which we reproduce. The house brought from Yakutsk proved to be comfortable and warm. It has been erected at the Sagastyr arm of the Lena, on Sagastyr Island (in 73° 22′ 30″ N. lat., and 144° 14′ 46″ E. long.); the name of this island is very significant: it means "it blows away." Galleries of planks have been erected behind the house to connect it with four pavilions for instruments. Besides the coal that has been taken from Yakutsk, the station has a good supply of fuel in the driftwood scattered around the station. The Sagastyr arm of the Lena supplies the inhabitants of the station with fresh fish. The health of all the members is satisfactory. Dr. Bunge received a contusion to a rib during the journey, but he is now well, and is besieged by indigenes, who come to him for medical help. Several Tungus families stay at one and two miles' distance from the station, and they are on the best terms with the meteorologists. The temperature is very low and, as there is no snow, the prospects are not very brilliant. The soil is frozen to a great depth, and cracks; the rivers and lakes are covered with a thick sheet of ice, so that the water beneath the ice is shallow, and the fish are in want of air to breathe. The food for the reindeer is frozen. Even at Yakutsk there was but one inch of snow on December 16, and a great inundation is expected for the spring, as well as epidemics, which are said usually to follow inundations.

As to the journey from Bulun to Sagastyr, it was performed not without difficulties. On August 6 a fresh west wind compelled the boats to stop on unfavourable ground, and the wind blowing with increasing force, it soon turned out a strong storm, blowing from north-west on August 9. The boats were thrown aground close by the banks of the river, and filled with water. The waves rolled above their decks. The chief instruments were, however, safe, as they were landed in time. On August 19 the expedition reached the Ketakh settlement, seven

miles south of the signal usually drawn on the maps of the delta of the Lena. Three days later the expedition chose Sagastyr Island as the place for the station, and began to erect the building and arrange the instruments.

Russian Meteorological Station at Sagastyr, at the mouth of the Lena, 73° 22′ 30″ N. lat., 144° 14′ 46″ E. long.

The house of the station is obviously very small; and when looking at Mr. Schütze's sketch of this small building, lost amidst the snow-plain, far from any communication with the civilised world, one cannot but admire the devotion of those who have willingly submitted to remain in these inhospitable latitudes for scientific purposes.

THE AURORA BOREALIS

AMONG the numerous varieties of the aurora borealis or northern light, there is one of particular interest as regards the determination of the origin of this phenomenon. This variety, which was observed and reported upon in 1868 by the members of the Swedish Polar Expedition, takes the form of tiny flames or a phosphorescent luminosity, appearing during the winter months in the Polar regions, around projecting objects, viz. mountain cones and ridges. This phenomenon is so prominent that one need not be a scientist to discover it, and it was observed by our well-known philologist, Herr M. A. Castrén, during his journeys in Siberia. Herr Castrén's descriptions of the phenomenon are very minute, and exactly in accordance with its usual appearances, but his observations were, however, not known to me in 1868, and it was only on the return of the expedition that I heard of them. The observations made by the Swedish expedition at Spitzbergen led the Finnish Society of Science in 1871 to despatch an expedition, of which I was a member, to Lapland to ascertain if such a phenomenon could not be called forth, or at all events magnified, by mere mechanical appliances. And assuming that the aurora borealis in general, and the variety of the same just mentioned in particular, is caused by electric currents in the atmosphere, an apparatus of the following nature was erected on Luosmavaara, a mountain-top about 520 feet above the surface of the Lake Enare, in Lapland. It consisted of a number of fine points of copper wire laid out in the shape of a wreath two square metres in area, and connected by a circular wire of the same metal. This wreath was attached to a long pole, from the top of which a single copper wire (0·4 mm. in diameter) led to a galvanometer fixed in a room in the Enare vicarage, some two miles distant east, and from the galvanometer another copper wire led to a disk of platina in the earth.

When this circuit was closed, the galvanometer gave a deflexion, although faint. But on the very same night the apparatus was erected, viz. November 22, 1871, *there appeared an aurora*, which began with a single perpendicular column of light *above the top of the Luosmavaara!* This column was analysed with the spectroscope, and gave the usual yellow-green line, but whether the column was *on* or *behind* the mountain-top could unfortunately not be clearly ascertained. That it, however, had its origin from the apparatus described above appears to me, after the researches were made which I am about to detail, to be beyond a doubt. At the same time, on November 22, 1871, it was observed, when studying the spectrum of the flames which, on that day appeared around the mountain-tops more distinctly than usual, that the characteristic yellow-green line in the spectroscope was returned from nearly every object, as, for instance, the ice of a pond, the roof of a shed, and even, though faintly, from the snow in the immediate vicinity of the observatory. These observations led me to believe that I was within a sphere of electric discharge, whose radius extended considerably around the station.

This interpretation of mine has, however, not been generally accepted by students of the phenomenon, who, on the other hand, have explained the appearance as being an aurora reflected from the earth; but that this theory is erroneous will be clearly demonstrated by the researches detailed below.

In Baron Nordenskjöld's exhaustive investigations of the aurora borealis during the *Vega* expedition, he states that he was unable to discover this phosphorescent phenomenon which I have observed, and that he had noticed in the spectroscope, in connection with the same, a faint band near the line D; but this has nothing whatever to do with the auroral line. In order, however, to make it clear that I have not confused these two lines, I may state that already in 1871 I observed the absorption-band in question, as will be seen from my work at the time on the aurora borealis and the auroral spectrum. In these researches I determined the wave-length of this line, and as the latter is only apparent in daylight or moonshine, while my observations were without exception made in the dark, it is perfectly clear that this line or band has nothing in common with the auroral one. The two lines are, in fact, of such a different character that they cannot

be confused for a moment by any one who has had an opportunity of comparing them simultaneously.

During the period which has elapsed since 1871 my efforts have been bent on the closest study of the aurora borealis, and an accidental discovery that a Geissler tube may produce certain forms of light without being in direct connection with either pole of an electric battery further stimulated my attention. This led to the result that the electric current emanating from the pole of an electric apparatus, while the other is connected with the earth, can be made to traverse a layer of air of *ordinary* density without producing any light at all; but when, on the other hand, it encounters a layer of *very thin* air, the luminous phenomenon will at once appear. These researches led me to construct an auroral apparatus for demonstrating this phenomenon as it appears in nature. The knowledge I have gained of the aurora during my continued labours and the above-mentioned observations in particular, made me conclude that an attempt to produce the auroral phenomenon in the very lap of nature by aiding the action of her own forces, ought to give important results and also originate a method for the future study of the phenomenon. In consequence of this idea I made the proposition to the International Polar Congress which I attended at St. Petersburg in 1881, to erect a station at Sodankylä to follow up my researches, although the results might perhaps be of negative value.

The Experiments on Oratunturi.—For the purpose of carrying out the experiment suggested above, the Finnish Polar Expedition was comparatively well equipped, the Physical Faculty of the University at Helsingfors having contributed instruments as well as wire; but the former had to be slightly altered for the research in view. Circumstances, however, occurred which prevented my work being commenced until the end of November, 1882; and after having examined the country and made some preliminary experiments from the steeple of Sodankylä Church, situated close to our observatory, I determined to erect the apparatus on the summit of the Oratunturi Mountain, some twelve miles from the observatory. The top was well suited for the purpose, although surrounded by rising copses of wood, which should, according to theory, be rather detrimental to such experiments. The summit was determined by barometrical measurements to be 1070 feet above the town of Sodankylä. To lead the wire from Oratunturi to Sodankylä was, in consequence of the great distance, impossible, as there were neither wires nor insulators sufficient, and I had therefore to carry out the experiments as follows:—

On the summit of Oratunturi (lat. 67° 21′, long. 27° 17′·3 E. of G.), about 540 metres above sea-level, I laid out the instrument which I have named an "utströmnings" apparatus, *i.e.* a "discharging" apparatus. It consisted of a bare copper wire 2 mm. in diameter, fitted at every half metre with points soldered thereon. The copper wire was laid out in entwined squares, while the points were raised on poles 2½ metres high, provided with insulators, so that each inner coil was about 1·5 m. from the outer one. The apparatus covered a surface area of 900 square metres. From the inner end of this wire an insulated copper wire on poles with telegraph insulators led to the foot of the mountain, where a hut of pine branches was erected; here the wire was connected with a galvanometer, and from this another wire led to a zinc disk in the "earth," *i.e.* in a flowing spring. The elevation of the apparatus above the zinc disk was 180 metres, and the direction of the conducting wire from the mountain north-west to south-east.

From the first day the apparatus was finished, viz. December 5, there appeared almost *every* night a yellow-white luminosity around the summit of the mountain, *while no such luminosity was seen around any one of the others!* The flames were very variable in intensity, and in constant oscillation as those of a liquid fire. Three times it was tested, 2½ miles off in south-east, by a Wrede spectroscope (small size with two prisms), and it returned a faintly continuous spectrum from D to F, in which the auroral line $\lambda = 5569$ with soft variable intensity was observed. The galvanometer steadily gave the deflexions of a positive current from the "utströmnings" apparatus to the earth. The deflexion was so exceedingly variable that the needles were in constant motion when the circuit was closed. A Leclanché's element of ordinary size gave a deflexion which varied according as the positive pole was turned against the mountain or against the earth, but it was always measurable.

It was, however, impossible to continue the observations for any length of time, as hoar-frost quickly developed on the wires and the poles in large quantities, whereby the insulation became affected. The conducting wire from the mountain was of copper insulated with waxed cotton, and 0·8 mm. in diameter. This became so covered with hoar-frost that it broke under the weight in spite of the short distance between the supporting poles, viz. 25 metres. It was, therefore, necessary to examine its entire length before the experiments could be commenced, and as the temperature, as a rule, was under −30° C., our work was greatly impeded.

Although the deflexions, by their great variation in the electric current and perhaps, from changes in the electric forces or the imperfect insulation, cannot be of great scientific value, I subjoin them:—

December 13, 1882.—After several alterations of the galvanometer, and the right sensitiveness having been obtained, the result was, with open circuit: scale-reading[1] of position of equilibrium (*a*) 361·5; (*b*) 362·7; with closed circuit (*c*) 457·8 [or 95·8 parts of the metre = 3°·5, every part of the metre being 2′·2]. This deflexion constantly varied, and often descended to 30 parts of the metre, to rise suddenly again. The temperature was that day comparatively high, viz. −10° to −12° C. The air was hazy.

December 19, 1882.—Plane of equilibrium, 468·0; with closed circuit, 471·6; deflexion = 3·6 parts of the metre.

A Leclanché's element placed in the circuit gave—

1. Plane of equilibrium with open circuit ... ... 469·4
2. With the carbon pole against the earth ... ... 476·4
3. With the carbon pole against the mountain ... ... 467·9

Or the current from the atmosphere = 2·75 parts of the meter.
And the current from the element = 4·25 ,, ,,

The insulation was here worse than in the previous case, and the temperature very low, viz. −35° C.

From December 27 to 29 several experiments were also made, under which the deflexions of the current were greater or less than under the above.

With regard to the construction of the galvanometer it may be mentioned that the instrument consisted of an ordinary wooden frame constructed for the coiling of the wire, while a pair of astatic needles with a mirror could freely swing within the frame thus: one within and the other above the coil. At first the frame was coiled with copper wire 0·5 mm., insulated with indiarubber, but during the experiments this wire was replaced by another 0·4 mm., and insulated with silk impregnated with stearine. The arrangement of the needles was altered several times, but under the above-recorded experiments they were hung on two fine threads of cocoon silk about 20 cm. long and about 1·5 mm. apart. The deflexions were read with a tube and scale from a distance of 0·8 metre.

The Experiments at Pietarintunturi.—On this mountain (lat. 68° 32′·5, long. 27° 17′·3 E. of G.), 950 metres above the sea, a smaller "utströmnings" apparatus was erected in two parts, so that the inner one covered about 80 and the outer 320 square metres. In other respects it

[1] These figures refer to the reading of a divided metre-scale viewed by reflexion in the mirror of the galvanometer by the "subjective" method through a reading-telescope.—[Ed.]

was similar to the one at Oratunturi, but the galvanometer here was not so sensitive, as the needles had lost some of their astatic quality through the journey.

On December 29 there appeared above this apparatus *a single column of aurora some* 120 *metres in height!* Its plane was determined from several points, viz., S.S.W. to E.S.E., within an angle of 90° with the plane of the horizon, and there was not the slightest doubt of the aurora appearing just *above* the apparatus. No spectrum analysis was, however, made, as the question of the greatest moment on this occasion was to determine the plane of the column in relation to the apparatus. A faint aurora in the sky at the back of the mountain might perhaps have influenced the analysis; besides which another difficulty arose from the temperature being − 35°, and the instrument in consequence difficult to handle. But that a spectrum similar to the one at Oratunturi and the one of 1871 on the Luosmavaara would have been received I have not the slightest doubt.

The galvanic measurements were effected as follows:—First, the galvanometer was connected with the inner coil of the "utströmnings" apparatus, 80 square metres in area, when deflexion was observed; secondly, it was connected with the outer coil, 320 square metres in area; and thirdly, with both apparatuses combined, or 400 square metres in area.

The deflexions were, in consequence of the small sensitiveness of the galvanometer, weak; but it was clearly noticed that the current increased with the area of the apparatus. As the deflexions varied considerably, it was impossible to ascertain exactly their natural law, but it seemed apparent that the strength of the current was *proportionate to the surface area of the apparatus laid out.* The galvanometer used in this case was similar to the other, but not so sensitive. If I designate the inclinations at Oratunturi with O and those of Pietarintunturi with P, the relative proportion of the sensitiveness of the galvanometers would be

$$P = 0{\cdot}370,$$

with very nearly the resistance of 20 Siemens units. The metre was here divided into 1''·2. The following shows the results of the experiments:—

December 29, 1882.—With the inner coil, or an area of 80 square metres:—

First deflexion,	2·1	parts of the metre.
Second „	0·9	„ „
Third „	1·0	„ „
Fourth „	2·4	„ „
Fifth „	2·0	„ „

The temperature was on that day, as almost during the whole period of experimenting here, − 30°, or under. The air was clear.

December 31, 1882.—With the whole surface of the apparatus, or an area of 400 square metres—

First deflexion,	1·6	parts of the metre.
Second „	2·8	„ „
Third „	3·8	„ „
Fourth „	3·1	„ „
Fifth „	3·1	„ „

With a Leclanché's element the result was:—

1. With the carbon pole against the mountain deflexion = − 0·2
   With the zinc „ „ „ + 7·5
   Of which deflexion by the current from the atmosphere = 3·65
   And „ „ „ Leclanché's element = 3·85
2. With the carbon pole against the mountain deflexion = − 1·5
   With the zinc „ „ „ = 11·9
   Of which deflexion by the current from the atmosphere = 5·2
   And „ „ „ Leclanché's element = 6·7

The experiments with the different parts of the apparatus resulted as follows:—

1. Plane of equilibrium (*a*) 271·6, (*b*) 271·4 } = 271·5 open circuit.

Inner apparatus A = 80 square metres.

(*a'*) 271·5, (*b'*) 271·7 } = 271·6 closed circuit.

Plane of equilibrium (*c*) = 270·4 open circuit.

Deflexion from A = 0·6.

Outer apparatus B = 320 square metres.

(*a*) Plane of equilibrium = 270·4 open circuit.

(*a'*) „ „ 271·8, (*b'*) „ „ 271·1 } = 271·5 closed circuit.

(*b*) „ „ = 270·1 closed circuit.

Deflexion from B = 1·2.

Entire apparatus C = 400 square metres.

(*a*) Plane of equilibrium = 270·1 open circuit.

(*a'*) „ „ 270·9, (*b'*) „ „ 270·7 } = 270·8 closed circuit.

(*b*) „ „ = 269·7 open circuit.

Deflexion for C = 0·9.

During these experiments it was noticed that the first deflexion was always far greater than the subsequent double, constant ones, and I have therefore noted this one only. When the circuit was closed it was observed that the needle pair always was at rest in the plane of equilibrium.

2. A. Plane of equilibrium 269·7 open circuit.
   (*a'*) „ „ 270·8 closed circuit, 1st defl. 277·0
   (*b*) „ „ 269·8 open circuit.
   Deflexion for A = 1·0 ... ... 1st defl. = 7·2
   B. (*a*) Plane of equilibrium 269·8 open circuit.
   (*a'*) „ „ 271·3 closed circuit, 1st defl 281·0
   (*b*) „ „ 270·4 open circuit.
   Deflexion for B = 1·2 ... ... 1st defl. = 11·8
   C. (*a*) Plane of equilibrium 270·4 open circuit.
   (*a'*) „ „ 271·8 closed circuit, 1st defl. 284·9
   (*b*) „ „ 270·4 open circuit.
   Deflexion for C = 1·4 ... ... 1st defl. = 14·5
3. A. (*a*) Plane of equilibrium 270·4 open circuit.
   (*a'*) „ „ 271·7 closed circuit, 1st defl. 278·2
   (*b*) „ „ 270·8 open circuit.
   Deflexion for A = 1·1 ... ... 1st defl. = 7·6
   B. (*a*) Plane of equilibrium 270·8 open circuit.
   (*a'*) „ „ 274·0 closed circuit, 1st defl. 282·0
   (*b*) „ „ 273·6 open circuit.
   Deflexion for B = 1·8 ... ... 1st defl. = 10·8
   C. (*a*) Plane of equilibrium 274·5 open circuit.
   (*a'*) „ „ 279·0 closed circuit, 1st defl. 292·3
   (*b*) „ „ 275·6 open circuit.
   Deflexion for C = 3·9 ... ... 1st defl. = 17·2

If these observations are connected we obtain:—

A = 80 square metres
B = 320 „
C = 400 „

	Deflexion.	1st. defl.	Deflexion.	1st defl.	Deflexion.	1st defl.
1.	0·6	—	1·2	—	0·9	—
2.	1·0	7·2	1·2	11·8	1·4	14·5
3.	1·1	7·6	1·8	10·8	3·9	17·2

If it now be considered that the current from the atmosphere was very variable, besides that the insulation was rather imperfect, the results of these experiments are not so reliable as might be desired. Still, this inference can safely be drawn from them, that the strength of the current *increases* with the area of the "utströmnings" apparatus or with the number of points, but the natural law of the increase I have not yet been able to determine. As will be seen from the subjoined figures the conductive power of the wire was that day very small, although the temperature was comparatively high, viz. at 1 a.m. − 18° C., but falling.

The entire apparatus (C) with one of Leclanché's elements:—

(*a*) Plane of equilibrium 273·1 open circuit.
(*a'*) „ „ 275·3 the zinc pole against the mountain.
(*b'*) „ „ 270·4 carbon „ „
(*b*) „ „ 270·1 closed circuit.

From this we obtain: the current from the atmosphere = 1·5, and from the element = 2·45, which figures show

the small conducting power of the wire, as well as the weak current from the atmosphere.

Another inference may be drawn from these observations. If we take the average of the results on December 31 on Pietarintunturi, when the whole apparatus was used, it will be 3·2 parts of the metre, and comparing this with that of December 19 on Oratunturi, when the atmospheric conditions were similar, which was 3·6 parts of the metre, and transform these into minutes, the result will be as follows: 3·6 parts of the metre at 2′·2 = 7·92; 3·2 parts of the metre at 1′·2 = 3′·84, but the sensitiveness of the galvanometer at Pietarintunturi was only 0·36 of that at Oratunturi = 0·37, and the area of the apparatus in the former 200 square metres against 900 in the latter, and further, assuming that the current increases in proportion to the area of the apparatus, we shall have:

$$\frac{3'{\cdot}84}{0{\cdot}36} \; \frac{900}{400} = 24'{\cdot}0.$$

And the deflexion 3′·84 being reduced to the same galvanometer sensitiveness and the same area of apparatus, the actual result is that the experiments at Oratunturi showed a deflexion *three times* greater than those at Pietarintunturi. The latter place is certainly situated a little higher than the former, but in my opinion the increase of the electric force lies in the fact that Oratunturi is in a higher latitude than Pietarintunturi, *i.e.* nearer the plane of the aurora borealis. Although the experiments recorded above suffer from inaccuracy on account of the imperfect insulation, I have come to the conclusion *that the electric current from the atmosphere increases rapidly with the latitude.*

The great deflexion which I obtained at Oratunturi on December 13, 1882, I do not consider refutes this inference, as the atmospheric conditions on this occasion were exceptional, viz. the temperature high and the air hazy.

The experiments in both places have, however, unfortunately been of a somewhat provisional character, which is due to the external impediments in our way. Thus, when experimenting at Oratunturi, the writer had to make a journey in the snow of 20 kilometres, viz. of four hours' duration, then to examine the apparatus on the summit, clean it from hoar-frost, and often repair it, with the thermometer at − 30° C. Then only could the experiments be commenced. It was only possible to work for five to eight minutes at a time, as it was necessary to thaw one's benumbed hands before a bonfire lit on the snow. At Pietarintunturi the road was certainly shorter, but, nevertheless, very fatiguing, as it was necessary first to climb a ridge about 1000 feet, and then journey about 3 kilometres.

These difficulties, and chiefly the imperfect insulations and the weakness of the wires at my disposal, compelled me to abandon experiments of this character.

SELIM LEMSTRÖM
Professor of the Helsingfors University

(*To be continued*)

NOTES

BESIDES Prof. Huxley the following English men of science have been elected Foreign Associates of the U.S. National Academy of Sciences:—Prof. J. C. Adams, Prof. Cayley, Prof. Sylvester, Prof. Stokes, Sir William Thomson, and Sir J. D. Hooker.

MR. HERBERT SPENCER has been elected a Corresponding Member of the Paris Academy of Moral and Political Sciences.

THE remarkable enthusiasm with which the project of the memorial to Charles Darwin was received in Sweden has already been noticed in our columns. The amount of the subscriptions collected, as was said, from all ranks, has just been received by the treasurer of the Darwin Memorial Fund. It is a sum of 382*l.* 12*s.* 6*d.*, the largest, we believe, that has been contributed by any foreign country, and a proof of the zeal on behalf of science that exists in the land of Linnæus.

WE are glad to learn that America has at length subscribed for a table at the Zoological Station at Naples. In view of the very considerable number of American students in European biological laboratories some surprise has naturally been felt that America has not hitherto been represented at Naples. President Carter and the trustees of Williams College are to be congratulated on having taken the lead in a matter the importance of which must be apparent to all who are interested in the progress of morphological study.

DR. WILLIAM CHAMBERS, the head of the eminent publishing firm, well deserves the honour of a baronetcy which he has just received, on account of the public services rendered by him to education and to social improvement throughout a long life; he is just the age of the century, we believe.

The public sale of the late Prof. J. Decaisne's library will take place in Paris from June 4 to 23 next. The catalogue of 480 pages, published by Labitte, of Paris, contains more than 5000 entries, classified according to subject by M. Vesque, assistant to the late M. Decaisne. It is probably one of the finest libraries in botany, horticulture, and general natural history which has been sold since the death of Jussieu. The catalogue contains a portrait of Decaisne and a biography by Dr. E. Bornet.

THE death is announced, at the age of seventy-one years, of Mr. James Young of Kellie, the "Sir Paraffin" of his old friend Livingstone. Mr. Young is best known in connection with his process of distillation of paraffin oil from bituminous coal, which attained great dimensions, and from which he realised a fortune. Mr. Young took a real and active interest in chemical research, and founded the Chair of Economic Chemistry in Anderson's University, Glasgow; he was a Fellow of the Royal Society.

THE departure of the Swedish Expedition to Greenland has been postponed to the 22nd, and Baron Nordenskjöld will join the *Sofia* at Gothenburg, instead of coming to Scotland.

A HYGIENIC exhibition was opened at Berlin on Saturday.

THE Society of Arts *conversazione* will this year be held in the buildings of the International Fisheries Exhibition; the Prince of Wales, the President of the Society, has intimated his intention of being present. The date is not yet announced.

IN connection with the recent discussion on the opening of picture galleries and museums on Sundays, the following facts relating to the Whitechapel Fine Art Exhibition are full of interest. This exhibition, which as may not be known to all our readers, is one which is open for thirteen days at Easter in one of the most desolate parts of this great metropolis. It consists of about two hundred pictures of the highest order of merit, which are placed at the disposal of a responsible committee by the artists or those who are fortunate enough to possess them. It is open gratuitously from ten in the morning until ten at night, except on Sundays, when the opening takes place at two o'clock, after morning service. This year, it will be seen from the numbers we give below, that no less than 34,644 of the poorest of the poor visited the pictures; and as they were to a very large extent "personally conducted" round the rooms by ladies and gentlemen who freely gave up their time to the work, the way in which they appreciated the pictures is thoroughly well known. The same men and women came again and again, bringing their friends to show them the pictures in which they themselves had taken the greatest interest. One of the most important points that we wish to urge now is, that on the last day the exhibition was open, which

was Sunday, between the hours of two and ten more than 3000 working men and women visited the collection, and we are informed that when the rooms were most crowded, there was always not only absolute order and good temper, but a reverence for the spirit of the place. This, we think, is a sufficient reply to those who say that if picture galleries and museums were opened on Sunday, they would not be visited. Seeing that a love of science and nature must be at the bottom of all true love for art, we feel ourselves bound to thank Mr. Barnett and those who have helped him in this humanising work; and as it is known with what sympathy artists and possessors of pictures placed them at the disposal of the committee, we think it a pity that the Whitechapel example is not more generally followed. It is not necessary to give the numbers for 1882, but we may just say that very nearly 10,000 more people visited the exhibition this year, which clearly shows that the interest taken in it is not a transient one, but one which increases from year to year. And the figures do not do justice to the success of the exhibition, for they mean something more than they would at an exhibition in the West End; the Whitechapel people went to see, and they made a business of seeing. The attendances were as follows:—

Tuesday	March 20	933
Wednesday	,, 21	2,094

AT the first meeting of the Sociological Section of the Birmingham Natural History and Microscopical Society for the study of Mr. Herbert Spencer's "System of Philosophy" held last week at the Mason College, the President (Mr. W. R. Hughes) explained that the new Section had originated in a wish to unite, for the purposes of mutual help, those who were already students of Mr. Herbert Spencer's system, but were unknown to each other; and to introduce to the synthetic philosophy those already engaged in some special biological study, but as yet unfamiliar with the principles common to all departments of natural history. He read a letter from Mr. Herbert Spencer expressing cordial sympathy with the objects of the Section, and adding some valuable suggestions as to the course of work to be undertaken by the Section. Whether we admitted or rejected Mr. Spencer's principles, the President said, there was no doubt of the wonderful influence they were exercising in this country, on the Continent, and in America. He enumerated many reasons why Birmingham was peculiarly adapted for the study of sociology, saying it was central, healthy, industrious, and earnest in all it undertook, active in reform, versatile in its trades, and therefore free from commercial panics, many-sided in religion, untiring in political activity. During the present century no town had exhibited a more remarkable social development, and therefore there was no town more fit for the study of sociology. Its development was of a type peculiar to a large industrial organisation, and was in marked contrast to that kind of development which would obtain under a military or ecclesiastical or agricultural organisation. Sociological generalisations made there might therefore be regarded as typical and unique. The President's address was followed by a discussion upon the first two chapters of the "Essay on Education."

MR. CLEMENT L. WRAGGE has undertaken to reorganise he meteorological work at the Ben Nevis Observatory, which he first commenced about two years ago, under the auspices of the Scottish Meteorological Society, and hopes to have the observing system reopened and in order by June 1. Mr. William Whyte, of Fort William (formerly assistant), will then receive further instruction from Mr. Wragge, and will take charge, having been appointed by the Society to carry on the work during the summer of the present year, in consequence of Mr. Wragge's intention to resume his travels in the course of a few months, and to revisit Australia. The voyage will be made a scientific one, and Mr. Wragge hopes to add largely to his natural history and ethnographical collections now at Stafford. He is arranging to carry on ocean meteorological observations on a large scale, following mainly the plan adopted by the *Challenger* expedition. Negretti and Zambra's new deep-sea thermometers are to be employed.

THE German gunboat *Hyäne* visited Easter Island last autumn, and determined its exact position, which was found to be 27° 10′ S. lat., and 109° 26′ W. long. The commander of the *Hyäne*, Capt. Geiseler, has reported minutely to the German Admiralty Office on the ethnology of the island, and this report is accompanied by numerous drawings of old colossal statues, stone houses, monuments, tombs of chiefs, &c. At the same time Capt. Geiseler made a collection of ethnological specimens which has been forwarded to Germany by way of Apia. The report is now printed and published by Mittler and Sohn (Berlin).

PROF. BASTIAN has been nominated honorary president of the Berlin Geographical Society. The following gentlemen have been elected as honorary members: Prof. von Richthofen, Dr. Gustav Nachtigal, Prof. Neumayer, Dr. Pogge, Dr. Buchner, and Lieut. Wissmann. The latter has also received the Society's Silver Knights-Medal.

AT Berlin an aurora borealis was observed on April 29 at 9 p.m. The phenomenon brightened up the whole sky, across which numerous bright red cloud-streaks seemed to shoot.

MR. ERNEST GILES, the explorer, contemplates organising a grand final expedition to traverse the remaining unexplored portions of the Australian continent, and to endeavour to discover some more trustworthy traces of Leichhardt.

IN the "Publications of the Massachusetts Society for the Promotion of Agriculture," Mr. S. H. Scudder has given an interesting account of the habits of a small moth (*Retinia frustrana*), and of the ravages caused by it on the pitch pine of Nantucket Island (*Pinus rigida*). Of late it has become so abundant as to threaten the total destruction of the pines. Like its European congeners its larvæ bore into the interior of the healthy young shoots and destroy them. The remedy recommended is the radical one of taking off from every tree those shoots that show themselves to be infested, but the author is fully alive to the difficulties attendant upon such a recommendation, especially those of expense. The insect has not yet made its appearance on the adjoining mainland, but it seems to have been observed in other more distant parts of the Eastern States. In Europe (and indeed in Britain) much damage is done to conifers (especially Scotch fir) by allied species, and they more especially infest quite young trees. Some of them principally affect the lateral shoots, and these, if not too numerous, cause no lasting injury to healthy young trees; but one especially (*R. turionella*) attacks the leading shoot, and is far more serious; in this case, if the tree be strong and healthy, a lateral shoot takes the place of the destroyed "leader," and recovery is effected by this means.

NEWS has at last been received from Dr. Pogge, the companion of Lieut. Wissmann, on his journey across Africa, and who remained in Africa after Wissmann left. It appears that

Dr. Pogge reached the Mukenge safely in September last, bringing large collections with him. He had written and sent to Malange for means for his return journey.

A REPORT on the Peter Redpath Museum, Montreal, the foundation of which was laid by the Marquis of Lorne in September, 1880, describes the opening ceremony in August, during the meeting of the American Association. Mr. Redpath in a very few words handed over the Museum to the University, and speeches were made by the Chancellor, Dr. Carpenter, Prof. Hall, and Dr. Dawson. Already collections have been placed in the Museum, which promises to become one of the first rank.

THE current number of the *Agricultural Students' Gazette*, edited by students at the Royal Agricultural College, Cirencester, contains an instructive article on Devonshire Orchards and Cider-making, by C. B. Northcote, a member of the College. Miss Ormerod contributes a paper on the Coffee Grub in Ceylon, embodying our information on this pest up to the present time, from information largely derived from a pamphlet by Mr. Haldane on the subject. Mr. Rutherford gives a concise paper on the Agriculture of the Cotswolds; Prof. Garside one on Glanders, adducing evidence that it is a germ disease due to a bacillus. There is also an interesting and instructive collection of chemical curiosities, answers to examination questions; and in addition reports on the experimental field plots, on the weather, on the amount of chlorine in the rain water of the district, and on many other more purely college matters. This magazine fully keeps up to its advanced standard, and has a value in a circle far wider than its immediate connection with the Agricultural College.

WE have received the *Proceedings of the Medical Society* of the Kazan University, which contains, besides purely medical papers, several valuable papers of general interest. We notice among them a lecture, by Prof. Scherbakoff, on carbonic and azulmic acids in the soil as a measure of the oxidation of its organic constituents. It is known that since more attention has been given to the sanitary conditions of different soils, Herr Pettenkofer has proposed to measure the amount of putrefied organic matter in the soil by the amount of carbonic acid it contains. Prof. Scherbakoff makes a complete analysis of the chemical and putrefactive processes that are going on in the soil, and comes to the conclusion that, unhappily, the carbonic acid does not give a measure either of the oxidating capacity of the soil or of the decomposition of the organic matter. The same conclusion is arrived at with regard to azulmic acid, which is formed only under the action of special ferments, as appears from the classical researches of MM. Schlesing, Müntz, and Pasteur, so that oxidation of the organic elements of the soil may go on on a large scale without azulmic acid appearing as a result of the process. We notice also a paper, by M. Orloff, on the influence of wet and dry chlorine upon different materials when used for disinfection, the author giving the results of a series of experiments on various linen, cotton, silk, and woollen stuffs. The tables of diseases at Kazan and in several districts of the province are also of great interest; they show, for instance, that the number of cases of malarial fever is really enormous, as it has reached, in the town of Kazan, the figure of 23,000 cases during five years. As to cattle and horse diseases, their number is still more striking, as every year the province loses no less than 4300 to 4600 head of horned cattle, to which must be added sometimes—as in 1877—3250 cattle and horses exterminated by the Siberian plague.

THE additions to the Zoological Society's Gardens during the past week include a Bonnet Monkey (*Macacus radiatus*) from India, presented by Mr. F. J. Wicks; a Ring-tailed Coati (*Nasua rufa*), a Kinkajou (*Cercoleptes caudivolvulus*) from Demerara, presented by Mr. Ernest Francis; a Herring Gull (*Larus argentatus*), British, presented by Mrs. Andrews; a Smooth Snake (*Coronella lævis*), European, presented by Mr. W. A. B. Pain; a Bateleur Eagle (*Helotarsus ecaudatus*) from Africa, two Germain's Peacock Pheasants (*Polyplectron germaini*) from Cochin China, purchased; a Bennett's Wallaby (*Halmaturus bennetti*), four Brown-tailed Gerbillus (*Gerbillus erythrurus*), born in the Gardens.

OUR ASTRONOMICAL COLUMN

D'ARREST'S COMET.—The following approximate positions of this comet are deduced from M. Leveau's elements:—

At Greenwich Midnight

	R.A. h. m. s.	Decl. ° ′	Log. Distance from Earth.	Log. Distance from Sun.
May 25	13 13 47	+13 8·9	0·2983	0·4312

THE OBSERVATORY OF RIO JANEIRO.—We have received the *Bulletin Astronomique et Météorologique de l'Observatoire Impérial de Rio de Janeiro* for January and February. In the first number are observations of the nucleus of the great comet of 1882 made by M. Lacaille. While stationed at Olinda (Pernambuco) for the observation of the transit of Venus, he remarked on November 16 a small nebulosity 6° south of the nucleus of the great comet: it was circular, and had a slight central condensation. On November 20 he saw it again; its aspect was the same as on the previous day, it had the same right ascension, but its declination was 1° further south. On November 22 and 26 it was observed in the same position as on the 20th. M. Lacaille believes that this small nebulosity was no other than a fragment of the nucleus of the great comet. On returning to Rio, he found on January 8, on examining this nucleus with the 10-inch equatorial and power of 500, that it was highly elongated and subdivided into four small nebulosities, the centres of which had the appearance of stars of the twelfth magnitude. The aspect of the fourth as compared with the others, was less condensed, but rather more lengthened out. On the following night he was surprised to find that the first nebulosity was no longer in the position that he had seen it on the 8th, but that it was situate outside the elongated nucleus, and its centre had lost the appearance of a star of the twelfth magnitude. The second nebulosity was precisely in the position of the day preceding. The fourth had sensibly approached the third. On January 10 the four nebulosities retained the same relative positions. Several days of cloudy weather followed, but on January 15 he found that there was a fifth nebulosity in the elongated nucleus. These changes are well shown in a lithograph accompanying M. Lacaille's observations. In the February number of the *Bulletin* are observations of the same comet, made at Athens by Dr. Julius Schmidt, as detailed in a letter addressed by him to the Emperor of Brazil. It relates chiefly to the nebulosities which were remarked by Dr. Schmidt in the vicinity of the nucleus of the great comet on October 9, 10, and 11, his drawings showing the fantastic forms presented by the nebulosities being lithographed.

THE OBSERVATORY OF MOSCOW.—Volume IX. (livraison i.) of *Annales de l'Observatoire de Moscou*, has been issued. Amongst the contents are a short paper by M. Bredichin on the resisting medium; Researches on the first comet of 1882 (Wells), and observations of the minor planet Victoria, taken in connection with others to be made at the Cape and other southern as well as northern observatories, as part of a plan organised by Dr. Gill, for the determination of a new value of the solar parallax. M. Bredichin compares the observed phenomena of the tail of the first comet of 1882 with the indications of theory.

KIELL ON TYCHO BRAHE'S NOVA 1572.—It has often been stated in our astronomical text-books, that John Kiell, Professor of Astronomy at Oxford, considered that the period of the celebrated star in Cassiopeia in 1572, was "about 150 years," or only half that which had been more generally assigned to it.

We suspect that this statement has arisen from a misconception of Kiell's words, while referring to the star in his *Introduction to the true Astronomy or Astronomical Lectures*, &c., the first English edition of which appears to have been published in 1721. In the third edition, 1739 (which is before us), at p. 56, we read, after his reference to the phenomena in 1572, "Leovitius, from the history of those times, tells us that in the time of the Emperor Otho, about the year 945, a new star appeared in Cassiopeia, just such a one as was seen in his time in the year 1572. And he brings us another ancient observation—that there was likewise seen in the *northern* region of the heavens, near the constellation Cassiopeia, in the year 1264, an eminently bright *star*, which kept itself in the same place, and had no proper motion. It is probable that these two stars might have been the same with that which was seen by Tycho, and that in about 150 years the same star may again make its appearance."

It will be remarked that Kiell makes no reference to any star seen midway between 945 and 1264, nor between 1264 and 1556, and it seems his meaning is clear, that Tycho's star, with a period of some 300 years, might make its appearance again "in about 150 years" from the time at which he wrote, as it might do were its changes accomplished in about three centuries. The misinterpretation of Kiell's words has led to his being credited with the opinion that the period is about 150 years, an idea which he probably never intended to express.

ELECTRICITY APPLIED TO EXPLOSIVE PURPOSES[1]

IN introducing the subject the lecturer indicated the principal advantages which it had been early observed would result from a certain mode of firing explosive charges by electric current instead of by the ordinary fuzes, the best of which had inherent defects, greatly limiting their use for any but the simplest operations. He traced the history and development of electric firing from the crude experiments of Benjamin Franklin, about the year 1751, through the various stages in which frictional electricity, volta-induction apparatus, and magnetoelectric machines had supplied the means of generating the current, the tendency of late years being to revert to a modified form of voltaic battery for one class of work, and to employ dynamo-electric machines for another class. The history and development of the low-tension or wire fuze, and of the various fuzes employed with electric currents of high tension, were also discussed, and their relative advantages, defects, and performances were described.

The only sources of electricity which at present thoroughly fulfilled the conditions essential in the exploding-agent for submarine mines were constant voltaic batteries. They were simple of construction, comparatively inexpensive, required but little skill or labour in their production and repair, and very little attention to keep them in constant good working order for long periods, and their action might be made quite independent of any operation to be performed at the last moment.

When first arrangements were devised for the application of electricity in the naval service to the firing of guns and so-called outrigger charges, the voltaic pile recommended itself for its simplicity, the readiness with which it could be put together and kept in order by sailors, and the considerable power presented and maintained by it for a number of hours. Different forms of pile were devised at Woolwich for boat and ship use, the latter being of sufficient power to fire heavy broadsides by branch circuits, and to continue in a serviceable condition for twenty-four hours, when they could be replaced by fresh batteries, which had in the meantime been cleaned and built up by sailors.

The Daniell and sand batteries first used in conjunction with the high-tension fuze for submarine mining service were speedily replaced by a modification of the battery known as Walker's, which was after some time converted into a modified form of the Leclanché battery.

The importance of being able to ascertain by tests that the circuits leading to a mine, as well as the fuzes introduced into that circuit, were in proper order, very soon became manifest; and many instances were on record in the earlier days of submarine mining of the disappointing results attending the accidental disturbance of electric firing arrangements, when proper means had not been known or provided for ascertaining whether the circuit was complete, or for localising any defect when discovered.

The testing of the Abel fuze, in which the bridge, or igniting and conducting composition, was a mixture of the copper phosphide and sulphide with potassium chlorate, was easy of accomplishment (by means of feeble currents of high tension), in proportion as the sulphide of copper predominated over the phosphide. Even the most sensitive might be thus tested with safety; but when the necessity for repeated testing, or even for the passing of a signal through the fuze, arose, as in a permanent system of submarine mines, the case was different, this fuze being susceptible of considerable alterations in conductivity on being frequently submitted to even very feeble test-currents, and its accidental ignition by such comparatively powerful test- or signal-currents as might have to be employed, became so far possible as to create an uncertainty which was most undesirable.

Hence, and also because the priming in these fuzes was liable to some chemical change detrimental to its sensitiveness, unless thoroughly protected from excess of moisture, another form of high-tension fuze, specially adapted for submarine mining service, was devised at Woolwich. This, though much less sensitive than the original Abel fuze, was sufficiently so for service requirements, while it presented great superiority over the latter in stability and uniformity of electric resistance; and, though not altogether unaffected by the long-continued transmission of test-currents through it, the efficiency of the fuze was not affected thereby.

Although high-tension fuzes presented decided advantages in point of convenience and efficiency over the earlier form of platinum wire fuze, the requirements which arose, in elaborating thoroughly efficient permanent systems of defence by submarine mines, and the demand for a battery for use in ships which would remain practically constant for long periods, caused a very careful consideration of the relative advantages of the high- and low-tension systems of firing to result in favour of the employment of wire fuzes for these services. In addition to the disadvantages pointed out there was an element of uncertainty, or possible danger, in the employment of high-tension fuzes, which, though partly eliminated by the adoption of voltaic batteries, in place of generators of high-tension electricity, might still occasionally constitute a source of danger, namely, the possibility of high-tension fuzes being accidentally exploded by currents induced in cables, with which they were connected, during the occurrence of thunderstorms, or of less violent atmospheric electrical disturbances.

Experiment, and the results obtained in military service-operations, had demonstrated that if insulated wires, immersed in water, buried in the earth, or even extended on the ground, were in sufficient proximity to one another, each cable being in circuit with a high-tension fuze and the earth, the explosion of any of the fuzes by a charge from a Leyden jar, or from a dynamo-electric machine of considerable power, might be attended by the simultaneous ignition of fuzes attached to adjacent cables, which were not connected with the source of electricity, but which become sufficiently charged by the inductive action of the transmitted current. It therefore appeared very possible that insulated cables extending to land- or submarine-mines, in which high-tension fuzes were inclosed, might become charged inductively during violent atmospheric electrical disturbances to such an extent as to lead to the accidental explosion of mines with which they were connected. In a Report by von Ebner on the defence of Venice, Pola, and Lissa, by submarine mines, in 1866, he refers to the accidental explosion of one of a group of sixteen mines during a heavy thunderstorm, as well as to the explosion of some mines, by the direct charging of the cables, through the firing station having been struck by lightning. Two instances of the accidental explosion of tension fuzes by the direct charging of overhead wires during lightning discharges occurred in 1873 at Woolwich.

Subsequently an electric cable was laid out at Woolwich along the river bank below low-water mark, and a tension fuze was attached to one extremity, the other being buried. About eleven months afterwards the fuze was exploded by a charge induced in the conductor during a very heavy thunderstorm.

In consequence of such difficulties as these experienced in the special application of the high-tension fuzes to submarine purposes, the production of comparatively sensitive low-tension fuzes, of much greater uniformity of resistance than those employed in former years, was made the subject of an elaborate

[1] The fifth of the series of Six Lectures on the Applications of Electricity, delivered on Thursday evening, April 19, at the Institution of Civil Engineers, by Sir F. A. Abel, F.R.S., Hon.M.Inst.C.E.

experimental investigation by the lecturer. Different samples of comparatively thin wires, made from commercial platinum, showed very great variations in electrical conductivity. Very considerable differences in the amount of forging to which the metal, in the form of sponge, had been subjected, did not importantly affect either its specific gravity or its conductivity, and the fused metal had only a very slightly higher degree of conductivity than the same metal forged from the sponge. The conductivity of very fine wires could therefore be but slightly affected by physical peculiarities of the metal, and the considerable differences in conductivity observed in different samples of platinum were therefore chiefly ascribable to variations in the degree of its purity. It appeared likely that definite alloys might furnish more uniform results than commercial platinum; experiments were therefore made with fine wires of German silver and of the alloy of sixty-six of silver with thirty-three of platinum employed by Matthiessen for the reproduction of B.A. standards of electrical resistance. Both were greatly superior to ordinary platinum in regard to the resistance opposed to the passage of a current; German silver was in its turn superior to the platinum-silver alloy; although the difference was only trifling in the small lengths of fine wire used in a fuze (0·25 inch), while the comparatively ready fusibility of platinum-silver contributed, with other physical peculiarities of the two alloys, to reduce German silver to about a level with it. Moreover, the latter did not resist the tendency to corrosive action exhibited by gunpowder and other more readily explosive agents which had to be placed in close contact with the wire bridge in the construction of a fuze, while the platinum-silver alloy was found to remain unaltered under corresponding conditions. Experiments having also been made with alloys of platinum with definite proportions of iridium, the metal with which it is chiefly associated, very fine wires of an alloy containing 10 per cent. of iridium were eventually selected as eminently the best materials for the production of wire fuzes of comparatively high resistance and uniformity, this alloy being found decidedly superior in the latter respect as well as in point of strength (and therefore of manageableness in the state of very fine wire 0·001 inch in diameter) to the platinum-silver wire. The fuzes now used in military and submarine services were made with bridges of iridio-platinum wire containing 10 per cent. of the first-named metal.

The electrical gun-tubes in the navy were fired by means of a specially arranged Leclanché battery, and branch circuits worked to the different guns; in broadside firing it was important that the wire bridge of any one of the gun-tubes which was first fired should be instantaneously fused on the passage of the current, so as to cut this branch out of circuit; in this respect the comparatively fusible platinum-silver alloy appeared to present an advantage, hence the naval electrical fuzes were made with bridges of that alloy. Uniformity of electrical resistance had become a matter of such high importance in the delicate arrangements connected with the system of submarine mines, as now perfected, that the very greatest care was bestowed upon the manufacture of service electric fuzes and detonators, which were in fact made in all their details with almost the precision bestowed upon delicate scientific instruments, and the successful production of which involved an attention to minutiæ which would surprise a superficial observer.

One of the earliest applications of electricity to the explosion of gunpowder was the firing of guns upon proof at Woolwich by means of a Grove battery and a gun-tube, which was fired by a platinum wire bridge, a shunt arrangement being used for directing the current successively into the distinct circuits connected with the guns to be proved. When the high-tension fuze had been devised, gun-tubes were made to which it was applied, and an exploder was arranged by Wheatstone, having a large number of shunts, so that as many as twenty-four guns might be brought into connection with the instrument, and fired in rapid succession by the depression of separate keys connected with each.

The firing of cannon as time-signals was an ancient practice in garrison towns, but the regulation of the time of firing the gun by electrical agency from a distance appears first to have been accomplished in Edinburgh, where, since 1861, the time-gun had been fired by a mechanical arrangement actuated by a clock, the time of which is controlled electrically by the mean-time clock at the Royal Observatory on Calton Hill.

Shortly after the establishment of the Edinburgh time-gun, others were introduced at Newcastle, Sunderland, Shields, Glasgow, and Greenock. The firing of the gun was arranged for in various ways; in some instances it was effected either direct from the Observatory at Edinburgh, or from shorter distances, by means of Wheatstone's magnetoelectric exploders. At present there were time-guns at West Hartlepool, Swansea, Tynemouth, Kendal, and Aldershot, which were fired electrically, either by currents direct from London, or by local batteries, which were thrown into circuit at the right moment by means of relays, controlled from St. Martin's-le-Grand.

About thirteen years ago the electrical firing of guns, especially for broadsides, was first introduced into the navy, with the employment of the Abel high-tension gun-tube and voltaic piles. The gun-tubes then used were manufactured originally for the proof of cannon and for experimental artillery operations, and were of very simple and cheap construction. Experience proved them to be unfitted to withstand exposure to the very various climatic influences which they had to encounter in Her Majesty's ships, and in store in different parts of the world. The low-tension gun tubes, having a bridge of very fine platinum-silver wire, surrounded by readily ignitible priming composition, was therefore adopted as much more suitable for our naval requirements.

The arrangements for broadsides or independent firing, and also for the firing of guns in turret-ships, had been very carefully and successfully elaborated in every detail, including the provision of a so-called drill- or dummy electrical gun-tube, which was used for practice and refitted by well instructed sailors. The firing-keys, and all other arrangements connected with electrical gun-firing, were specially designed to insure safety and efficiency at the right moment.

The electric detonators for firing outrigger-torpedoes, or for other operations to be performed from open boats, corresponded, so far as the bridge was concerned, with the naval electric gun-tubes, and were fired with a specially fitted Leclanché battery. These electric appliances were now distributed throughout the navy, and the men were kept, by instruction and periodical practice, well versed in their use.

The application of electricity to the explosion of submarine mines, for purposes of defence and attack, received some attention from the Russians during the Crimean War, under the direction of Jacobi; thus a torpedo, arranged to be exploded electrically when coming into collision with a vessel, was discovered at Yeni-Kale during the Kertsch expedition in 1855. Some arrangements were made by the British at the conclusion of the war to apply electricity to the explosion of large powder-charges for the removal of sunken ships, &c., in Sebastopol and Cronstadt Harbours. In 1859, a system of submarine mines, to be fired through the agency of electricity by operators on shore, was arranged by von Ebner for the defence of Venice, which, however, never came into practical operation. Early in 1860 Henley's large magnetoelectric machine, with a supply of Abel fuzes, and stout indiarubber bags, with fittings to resist water-pressure, was despatched to China for use in the Peiho River, but no application appeared to have been made of them. The subject of the utilisation of electricity for purposes of defence, however, did not receive systematic investigation in England or other countries until some years afterwards, when the great importance of submarine mines, as engines of war, was demonstrated by the number of ships destroyed and injured during the war in America.

The application of electricity to the explosion of submarine mines was very limited during that war, but arrangements for its extensive employment were far advanced in the hands of both the Federals and Confederates at the close of the war, men of very high qualifications, such as Capt. Maury, Mr. N. J. Holmes, and Capt. McEvoy having worked arduously and successfully at the subject.

The explosion of submerged powder-charges, by mechanical contrivances, either of self-acting nature or to be set into action at desired periods, was accomplished as far back as 1583, during the siege of Antwerp, by the Duke of Parma, and from that period to 1854 mechanical devices of more or less ingenious and practicable character had been from time to time applied to some small extent, in different countries, to the explosion of torpedoes. The Russians were the first to apply self acting mechanical torpedoes with any prospect of success, and had the machines used for the defence of the Baltic been of larger size (they only contained 8 or 9 lb. of gunpowder), their presence would probably have proved very disastrous to some of the English ships which came into collision with and exploded them.

Various mechanical devices for effecting the explosion of torpedoes by their collision with a ship were employed by the Americans, a few of which proved very effective. But although in point of simplicity and cost, a system of defence by means of mechanical torpedoes possessed decided advantages over any extensive arrangements for exploding submarine mines by electric agency, their employment was attended by such considerable risk of accident to those at whose hands they received application that, under many circumstances which were likely to occur, they became almost as great a source of danger to friend as to foe.

The most important advantages secured by the application of electricity as an exploding-agent of submarine mines were as follows:—They might be placed in position with absolute safety to the operators, and rendered active or passive at any moment from the shore; the waters which they were employed to defend were therefore never closed to friendly vessels until immediately before the approach of an enemy; they could be fixed at any depth beneath the surface (while mechanical torpedoes must be situated directly or nearly in the path of a passing ship), and they might be removed with as much safety as attended their application.

There were two distinct systems of applying electricity to the explosion of submarine mines. The most simple was that in which the explosion was made dependent upon the completion of the electric circuit by operators stationed at one or more posts of observation on shore; such a system depended, however, for efficiency, on the experience, harmonious action, and constant vigilance of the operators at the exploding- and observing-stations, and was, moreover, entirely useless at night, and in any but clear weather.

The other, which might also be used in conjunction with the foregoing, was that of self-acting mines, exploded either by collision with the ship, whereby circuit was completed through the inclosed fuze, or by the vessel striking a circuit closer, whereupon either the mine, moored at some depth beneath, was at once fired, or the necessary signal was given to the operator on shore.

Continental nations had followed in our footsteps, in providing themselves with equipments for defensive purposes by submarine mines, and the Danes, Swedes, and Norwegians had pursued the subject of submarine mines with special activity and success.

In the United States the subject of the utilisation of electricity as an exploding-agent for war purposes was being actively pursued, and important improvements in exploding instruments, electric fuzes, and other appliances had been made by Smith, Farmer, Hill, Striedinger, and others already mentioned, while no individual had contributed more importantly to the development of the service of submarine explosions than General Abbot, of the United States Engineers.

Illustrations of actual results capable of being produced in warfare by submarine operations had hitherto been very few; but of the moral effects of submarine mines there had already been abundant illustrations. In the war carried on for six years by the Empire of Brazil and the Republic of Uruguay and the Argentine Republic of Paraguay, the latter managed, by means of submarine mines, to keep at bay, for the whole period, the Brazilian fleet of fifteen ironclads and sixty other men-of-war. In the Russo-Turkish war, submarine mines and torpedoes were a source of continued apprehension; and the French naval superiority was paralysed, during the Franco-German war, by the existence, or reputed existence, of mines in the Elbe.

The application of electricity to the explosion of military mines, and to the demolition of works and buildings, had been of great importance in recent wars in expediting and facilitating the work of the military engineer. The rapidity with which guns, carriages, &c., were disabled and destroyed by a small party of men who landed after the silencing of the forts at Alexandria, illustrated the advantages of electrical exploding arrangements, combined with the great facility afforded for rapid operations by the power possessed of developing the most violent action of gun-cotton, dynamite, &c., through the agency of a detonator.

The application of electricity to the explosion of mines for land-defences during active war was not an easy operation, inasmuch as not only the preparation of the mines but also the concealment of electric cables and all appliances from the enemy entailed great difficulties, unless the necessary arrangements could have been made in ample time to prevent a knowledge of them reaching the enemy.

But few words were needed to recall to the minds of civil engineers the facilities which the employment of electricity to explosive purposes afforded for expediting the carrying out of many kinds of works in which they were immediately interested. Electrical blasting, especially in combination with rock-boring machines, had revolutionised the operation of tunnelling and driving of galleries; and although in ordinary mining and quarrying operations the additional cost involved in the employment of fuzes, conductors, and the exploding-machine was not unfrequently a serious consideration, there were, even in those directions, many occasions when the power of firing a number of shots simultaneously was of great importance. There was little doubt, moreover, that accidents in mining and quarrying would be considerably reduced in number if electrical blasting were more frequently employed.

The conveniences presented by electric firing arrangements under special circumstances were interestingly illustrated by a novel proceeding at the launch of a large screw steamer at Kinghorn in Scotland, which was recently accomplished by placing small charges of dynamite in the wedge-blocks along the sides of the keel and exploding them in pairs, hydraulic power being applied at the moment that the last wedge was shot away.

In the deepening of harbours and rivers and in the removal of natural or artificial submerged obstructions, the advantages of electric firing were so obvious that extended reference to them was unnecessary.

A substitute for electrical firing which had been applied with success to the practically simultaneous firing of several charges consisted of a simple modification of the Bickford fuze, which, instead of burning slowly, flashed rapidly into flame throughout its length, and hence had received the name of instantaneous fuze or lightning fuze. The fuze burned at the rate of about 100 feet per second; it had the general appearance of the ordinary mining fuze, but was distinguished from the latter by a coloured external coating. Numerous lengths of this fuze were readily coupled up together so as to form branches leading to different shot-holes, which might be ignited together so as to fire the holes almost simultaneously. In the navy this fuze was used as a means of firing small gun-cotton charges to be thrown by hand into boats when these engaged each other, the fuze being fired from the attacking boat by means of a small pistol, into the barrel of which the extremity was inserted.

THE IRON AND STEEL INSTITUTE

THE annual meeting of this society took place at the Institution of Civil Engineers on May 9, 10, and 11 last. On the first day the chair was taken by the retiring president, Mr. Josiah T. Smith, but after some formal business had been gone through he vacated it in favour of the president elect, Mr. B. Samuelson, M.M., F.R.S. The latter proceeded to read an able address, dealing mainly with the great progress which had taken place in the iron and steel industries since the Institute was founded in 1869. He remarked on the very large makes of pig iron which were now going on in American blast furnaces, and stated that these were found to be economical even as regards fuel and wear and tear of the lining. He then dwelt at some length on improvements in the manufacture of coke, especially with a view to recovery of the waste products. The deterioration which was feared would result as regards the coke itself had not appeared in the case of the Simon-Carvés ovens, worked by Messrs. Pease and Co., who were recovering oil and tar to the value of 4*s.* 2*d.* per ton of coal. Against this was to be set increased expenses to the amount of 1*s.* 4*d.* per ton of coke, and also interest on first cost and maintenance. He further referred to the Jameson process lately described before the Institution of Mechanical Engineers, and observed that this principle was being applied to recover oil and ammonia from smouldering waste-heaps at the pit bank. Passing on to the manufacture of steel he spoke with much approval of the Bicheroux gas puddling furnaces at Ougrée in Belgium, where gas obtained from slack was used for puddling, and gave more heat for steam-raising purposes than the old system. Speaking of the future demand for iron and steel, he pointed out that the United States had fifty times and Russia five times as many miles of railway per million of people as had our Indian Empire; and strongly urged the further development of railways in the latter country. The address also touched upon many other points connected with iron and steel, such as the

increased production of Bessemer and Siemens steel, the great diminution in their price, the immense increase in shipbuilding, the proposed improvements in the patent law, and the better relations now existing between masters and workmen. At the conclusion of his address the president presented the Bessemer medal to Mr. J. G. Snelus of Workington for his achievements in introducing the basic system for the making of steel. A similar medal, bestowed upon Mr. S. G. Thomas, was reserved until his return to England.

The meeting then took up the discussion on a paper by Mr. Snelus on the Chemical composition and testing of steel rails. This paper was read at the Vienna meeting of the Institute and its discussion postponed. Mr. Snelus now added particulars of a new test for the hardness of rails, which consisted in driving a uniform punch under uniform pressure into a piece of the rail, and measuring the depth of the hole produced. Various experiments had satisfied him that this depth would be inversely proportional to the hardness of the rail. M. Cazés, engineer to the Lyons Railway, read a very long note in French on the same subject, the point of which was that, as he maintained, the wearing power of the rail depends not only on its chemical composition but also on the temperature in rolling and the amount of compression which it has experienced while being rolled. He stated that a percentage of carbon varying from ½ to 1 per cent. was found in France to give the best result for rail heads.

Two papers were then taken together: the first of these was by Mr. Wm. Parker (Chief Engineer and Surveyor of Lloyd's), on the Use of steel castings in lieu of steel and iron forgings for ship and marine engine construction. This paper gave the results of an important investigation made by Lloyd's Registry into the applicability of steel castings to heavy articles such as crank shafts, sternposts, &c., which had hitherto been chiefly made in forged iron. The result was to convince the Committee that such constructions can be made of cast steel quite as good for the purposes intended as those of wrought iron, and without the uncertainty which always exists more or less in large iron forgings. The making of such castings is mainly in the hands of three firms, who, however, differed very materially in their views of the best mode of proceeding, especially as to whether the metal should be melted in crucibles or in the ordinary open hearth. At Terre Noire, where such castings are also made, great importance is attached not only to annealing but also to tempering them in oil; and the author gave particulars of experiments made on this subject, which showed that such treatment had a marked effect in increasing the strength of the specimens whilst slightly diminishing their ductility. Reference was made to the distinction between forged steel and cast steel, and a number of experiments were quoted on similar bars of both these materials and also of wrought iron. In these experiments the strength of the cast steel specimens was in every case greater than those of the wrought iron, whilst the ductility was about the same. With the forged steel the tensile strength was designedly made low, but the ductility was very high. Taking the product of the ultimate strength and ultimate elongation as representing roughly the quality of the material, it appears that the cast steel is one-third higher than wrought iron on an average, whilst the forged steel is three times as high. Transverse tests, both by steady pressure and by impact, and also torsion tests, gave results practically similar. Finally some experiments made by Mr. James Neilson on steel, partly as cut from the ingot and partly as hammered or rolled down to a comparatively small thickness, showed that the latter process produced a very decided increase both as to strength and ductility in some cases, although the results were not very uniform. For casting crank shafts and similar work Lloyd's Committee considered that the tensile strength of the steel should not exceed thirty tons per square inch, and that a piece 1¼ inch square should bend cold through an angle of 90 degrees.

The second paper was by Mr. Wm. D. Allen, of Henry Bessemer and Co., and was on Bessemer steel in its cast and unwrought state. The object of this paper was to dispel the idea that Bessemer steel is not a safe material for casting on account of the frequent presence of cavities or blowholes within it. From daily experience Mr. Allen affirms that perfectly sound castings can be made from Bessemer steel, provided that the ladleful is alloyed either with ferromanganese or with some iron ore rich in silicon. In order that this alloy may mingle perfectly with the steel, the ladle should be violently stirred by means of an agitator, already described to the Institute. Of such steel, the reader stated that nearly 500 hydraulic cylinders had been made, and tested up to two, three, or even four tons per square inch.

An interesting discussion followed these papers. Mr. James Riley doubted whether the crucible process produced a result more uniform than the open hearth, and spoke strongly in favour of annealing and tempering in oil. He also doubted whether the work put upon forged steel gives the advantage which was claimed for it. Mr. Hall (Messrs. Jessop and Sons, of Sheffield) defended the crucible process, but disparaged Bessemer castings. Sir Henry Bessemer, however, considered that the agitator had overcome the difficulty which previously existed in making sound castings in his steel, while Sir Wm. Siemens observed on the danger that castings may contract unequally in cooling, and on its complete cure by annealing. He suggested an explanation for the curious fact of the advantage due to oil-hardening, namely, that the oil produced a compression of the outer layers, which acted on the rest of the mass, and was of more effect than any mechanical pressure could be.

The second day's proceedings opened with the reading of two papers on the vexed question of hot blasts and high furnaces. The first was by Mr. Wm. Hawdon, who gave the particulars of comparative experiments made on one of Messrs. Samuelson's furnaces at Middlesborough, which had been supplied alternately with blast from pipe stoves at 990° F. and with blast from firebrick stoves at 1400° F. The final result was an increase in the make per week from 400 to 458 tons of pig, a diminution in the coke per ton from 23·8 to 22·3 cwt., and at the same time an improvement in the quality of experiments at the various temperatures of blast between these two limits showed a gradual rate of improvement. At the same time the temperature of the escaping gases was diminished from 468° to 448°, and the volume, of course, was diminished also. Comparing the two modes of heat, he showed that the area of heating surface in proportion to the cubic capacity of the stove was much greater in the firebrick than in the pipe stove, giving a corresponding improvement in effect, and that the gases escaping from the chimney, which in the pipe stoves had a temperature of 1240° F., in the brick stoves were as low as 250° F. The result was to effect a very considerable saving of gas used for heating the blast, which gas may, of course, be utilised for steam-raising or other purposes.

The second paper was by Mr. I. Lowthian Bell, F.R.S., and dealt with the Value of successive additions to the temperature of air used in smelting iron. This paper was to some extent a rejoinder to those of Mr. Charles Cochrane, recently read before the Institution of Mechanical Engineers. Mr. Bell first considered the proposed application of hydrogen, or what is called water gas, to the blast furnace, and showed that this could produce no advantage in saving of heat. He then dealt with the question of the possible economy of coke in an ordinary furnace, and reiterated that a limit was placed to such economy by the fact that when the escaping gas consists of carbonic oxide and carbonic acid in the proportion of 2 to 1, these combined gases can no longer produce any effect in reducing iron ore. Hence the very great saving of fuel which had at first been effected by enlarging the size of the furnaces and increasing the heat of the blast, had now nearly reached its limit; which Mr. Bell still held to be represented by a capacity of about 15,000 cubic feet, and a temperature of about 1000° F. He dealt with the suggestion that the heating of the blast could be advantageously used to replace the heat evolved in burning carbonic oxide and carbonic acid; and showed that to effect any great improvement in this particular would require blasts of too high temperature to be practically available. He commented upon the results with the furnace at Messrs. Samuelson's works, and considered that the increase in the make must be due to the increased quantity of blast rather than to its higher temperature. He admitted a saving in coke of about 1 cwt., but he observed that on the other hand the furnace was driven very slowly, only supplying about half the weight of pig iron per cubic foot of capacity which was usually supplied by the furnaces in the Cleveland district.

Mr. Bell's position was strongly assailed by Mr. Charles Cochrane; but although the questions between them were still further debated, it can hardly be said that they are completely settled. The problem is one which involves several independent factors, and a variation in any one of these might produce a large effect on the final result. It was so far fortunate that on this occasion the question of stoves and of blast furnaces was considered together, and not separately, as is often the case; but

there are still other matters to be taken into consideration. One of these, for instance, is the distance between the tuyeres at the bottom of the furnace. Mr. Cochrane confidently predicted that an alteration in this particular would effect a very important saving in Messrs. Samuelson's furnaces. The large economy actually realised by the use of brick stoves was commented upon by several speakers; but the advantage of increasing the capacity of furnaces appeared to be doubted by two very high authorities upon the subject, Mr. Edward Williams and Mr. E. Windsor Richards.

On Thursday afternoon the paper read was on the Northampton iron ore district, by Mr. W. H. Butlin. It gave an interesting description of this district, well known to travellers on the main line of the Midland Railway, in which, however, the deposits of ore have only been developed within the last thirty years. The paper also contained analyses of the ore, which is of a very variable character, and also of the limestone, slags, &c.

On Friday morning the first paper read was by Mr. John Stead of Middlesborough, on a New method for the estimation of minute quantities of carbon. The author had found that the colouring matter, which is produced by the action of dilute nitric acid upon white iron and steel, has the property of being soluble in potash and soda solutions, and that the alkaline solution has about two and a half times the depth of colour produced by the ordinary acid solutions. Hence it occurred to him that the colour-matter might be separated from the iron, as an alkaline solution, by simply adding an excess of sodium hydrate to the nitric acid solution of iron, and that the colour solution thus obtained might be used as a means of determining the amount of carbon present. This method is found to succeed well, as small a quantity as 0·03 per cent. of carbon being readily detected. The method of using it was described, and also experiments made to determine (1) the influence of heating the nitric acid solution for a longer or shorter time; (2) the effect of using an excess of nitric acid to dissolve the steel; (3) the effect on the solvent power of using a greater or less quantity of soda solution; (4) the effect of the presence of small quantities of chlorine. All these experiments proved satisfactory as regards the new process. An improved form of chromometer was also described.

The next paper was on the Production and utilisation of gaseous fuel in the iron manufacture, by Mr. W. S. Sutherland of Birmingham. It was of a somewhat discursive character, containing various suggestions, especially as to a method of making wrought iron by the converter process; but its chief object was to describe the production of a cheap form of heating gas, which the author has used largely for the welding up of boiler-flues, tubes, &c. In this process part of the fuel is burnt, as completely as possible, to carbonic acid and water, but the resulting heat is stored up partly in the remainder of the fuel and partly in regenerators, that in the regenerators being made to heat up to a sufficiently high degree a quantity of steam. This superheated steam is passed through the hot fuel, and forms with it carbonic oxide and hydrogen, which go away to be stored up and used. With this process about 55,000 cubic feet of gas is made per ton of Staffordshire coal, and at a cost of about 3*d*. per 1000 cubic feet, its heating power being about one-half that of coal gas. The author pointed out that it was most important to prevent as far as possible the formation of carbonic acid, and that for this a high temperature (say 1200° C.) was required.

The following papers were taken as read:—On Coal-washing machinery, by Mr. Fritz Baare; on the Tin-plate manufacture, by Mr. E. Trubshaw; and on Improvements in railway and tramway plant, by Mr. Albert Riche.

SCIENTIFIC SERIALS

American Journal of Science, April.—Review of De Candolle's origin of cultivated plants, with annotations on certain American species, by A. Gray and J. H. Trumbull.—Remarks on Glyptocrinus and Reteocrinus, two genera of Silurian crinoids, by C. Wachsmuth and F. Springer.—Smee battery and galvanic polarisation, by H. Hallock.—The age of the Southern Appalachians, by O. B. Elliott.—Evolution of the American trotting-horse, by W. H. Brewer.

IN the *Annalen der Physik und Chemie* for 1883, part i, Ernst Pringsheim has an elaborate paper on the theoretical and practical aspects of Crooke's radiometer. This is followed by essays on Stokes's law of fluorescence, by Ed. Hagenbach; on special cases of crystallisation, by E. Lommel; on the heat-conducting power of fluids, by L. Graetz; on the relation of specific heat in gases and vapours, by P. A. Müller; on the constant result of internal friction and galvanic conduction in relation to temperature, by L. Grossmann; and on A. Guebhard's proposed method of determining equipotential lines, by Hugo Meyer. Part ii. contains papers by O. Grotian on the power of electric conduction of some cadmium and quicksilver salts in liquid solutions; by W. C. Röntgen, on the change produced by electric power in the double fracture of quartz (continued in part iv.); by A. Kundt, on the optical character of quartz in the electric field; by H. Meyer, on the magnetising function of steel and nickle; by A. von Waltenhofen, on the history of recent dynamoelectric machines, with some remarks on the determination of the working powers of electromagnetic motors; by J. Wagner, on the tenacity of solutions of salts; by S. von Wroblewski, on the absorption of gases by fluids under high pressure; by A. Schuller, on distillation in vacuum; by K. R. Koch, on the elasticity of crystals of the regular system; by C. Bohn, on absolute masses; by E. Gerland, on the methods adopted by R. Kohlrausch in his researches in contact electricity. In part iii. papers are contributed by F. Neesen, on the specific heat of water; by E. Ketteler, on the conflicting theories of light (continued in part iv.); by W. G. Hankel, on the thermoelectric properties of helvine, mellite, pyromorphite, mimetesite, phenakite, pennine, strontianite, witherite, cerussite, titanite; by F. Niemöller, on the dependence of the electromotor power of a reversible element on the pressure exercised on its fluidity; by C. Tromme, on experimental researches in magnetism; by K. Vierordt, on sound measurement; by A. Ritter, on the constitution of gaseous bodies; by K. R. Koch, on a method of testing the micrometric screw. Part iv. contains papers by F. Kohlrausch, on the galvanic gauging of the surface coil of a wire bobbin; by C. Tromme, on electrical research; by M. Baumeister, on the experimental investigation of torsion elasticity; by E. Wiedemann, on thermochemical research; by G. Kirchhoff, on the theory of light radiation; by W. Wundt, on sound measurement.

Journal de la Physique, February.—On a spectroscope with great dispersion, by M. Cornu.—On the comparative observation of telluric and metallic lines, as a means of observing the absorbent powers of the atmosphere, by the same.—Researches on the photometric comparison of differently coloured sources, and in particular on the comparison of different parts of the same spectrum, by MM. Macé de Lepinay and Nicati.—On electric shadows and various connected phenomena (second article), by M. Righi.

Verhandlungen der k.k. Zool.-botan. Gesellschaft in Wien, 1882, Bd. xxxix. Heft 2 (March, 1883), contains:—Zoology.—Biological notes on some beetles belonging to the Dascyllidæ and Parnidæ, by Th. Beling.—On Platen's ornithological collections from Amboyna, by W. Blasius.—On a new tortoise, by J. v. Hornig.—On the genus Colias, by A. Keferstein.—On the skin glands in some larvæ, by Dr. Klemensiewicz (Plates 21 and 22).—On new Hymenoptera, by Fr. Kohl (Pl. 23).—On the Myriapods of Austrian-Hungary and Servia, by Dr. R. Latzel.—The butterfly fauna of Surinam, v., by H. B. Möschler (Plates 17 and 18).—On a new mite in the inside of the quill feathers in the hen, by Dr. C. Nörner (Plates 19 and 20).—On a collection of birds from Central Africa, sent by Dr. E. Bey, by A. v. Pelzeln.—On Pselaphidæ and Scydmænidæ, from Java, Borneo, and Central and South America, by E. Reitter.—On *Icaria scudderi*, by Dr. H. Weyenbergh.

THE *Atti* of the Roman *Accademia dei Lincei* for January and February, 1883, contains papers by E. Millosevich, on the ingress of Venus on the solar disk, December 6, 1882; by A. Lugli, on the mean variation of temperature in Italy, as affected by latitude and elevation; by A. Viola, on the relations of some physical properties of gaseous bodies under constant pressure and of constant bulk; by L. Pigorini, on barbaric stations still existing in the Emilian provinces; by Tommasi-Crudeli, on the malaria of the Tre Fontane district, which appears not to have been beneficially affected by the Eucalyptus plantations elsewhere found so efficacious; by S. Tacchini, on meteoric dust and the chemical analysis of the sands of the Sahara; by the same author, on Finlay's comet and on the new asteroid (232) discovered on February 1 by Palisa; by S. Brioschi, on the algebraic relations between the hyperelliptical functions of first order; by S. Ferrari, on the relations between the meteoric elements and some agricultural returns for the year 1880 in Italy.

THE *Rendiconti* of the *Reale Istituto Lombardo di Scienze e Lettere* for February and March, 1883, contains papers by G. Ascoli, on Irish glosses, especially those of the Ambrosian Codex; by M. E. E. Beltrami, on the theory of magnetic layers; by Z. Volta, on an unpublished drama of Luigi Ceretti; by G. A. Maggi, on the transmission of undulatory motion, and especially of luminous waves, from one isotropic medium to another; by P. F. Denza, on the observations of the transit of Venus made at the observatory of the Collegio Carlo Alberto in Moncalieri.

SOCIETIES AND ACADEMIES

LONDON

Royal Society, April 12.—"The principal cause of the large errors at present existing between the positions of the Moon, deduced from Hansen's Tables and observation; and the cause of an apparent increase in the secular acceleration in the Moon's mean motion required by Hansen's Tables, or of an apparent change in the time of the Earth's rotation," by E. J. Stone, F.R.S.

The errors in the lunar theory have been traced to the effects of changes in the *unit of time* which have, apparently unconsciously, been introduced, from time to time, into astronomy with changes in the adopted data.

The argument is clearly seen by a consideration of the different expressions for the longitudes of, what may be called, the mean sun which have been adopted for the determination of the sidereal times at mean noon.

If B, H, and V denote the longitudes of the mean sun according to Bessel, Hansen, and Le Verrier, we have for 1850, January 1, Paris mean noon, $+ t$

$$B = 280\ 46\ 36''{\cdot}12 + 1296027{\cdot}618184t + 0{\cdot}0001221805 \,.\, t^2$$
$$H = 280\ 46\ 43{\cdot}20 + 1296027{\cdot}674055t + 0{\cdot}0001106850 \,.\, t^2$$
$$V = 280\ 46\ 43{\cdot}51 + 1296027{\cdot}678400t + 0{\cdot}0001107300 \,.\, t^2.$$

In all these expressions the unit of time has been *supposed* to be a Julian year of 365·25 mean solar days. The constant differences 7″·08 and 7″·39 in $B-H$ and $B-V$ are not unimportant, for they introduce abrupt changes in the record of time; but the differences in the coefficients of t and t^2 show that the *same* unit of time cannot have been adopted in these expressions. The measure of time must be continuous; let, therefore, 1 and $(1 + x)$ be the units in B and H,

then $1296027{\cdot}618184 \,.\, t + 0{\cdot}0001221805t^2$
$$= 1296027{\cdot}674055t(1+x) + 0{\cdot}0001106850t^2(1+x)^2.$$

If, therefore, $n = 1296027{\cdot}674055$
$$x = -\frac{0{\cdot}055871}{n} + \frac{0{\cdot}000114955 \,.\, t}{n}$$

To reconcile B and H, therefore, x must contain a variable term. Similar remarks apply to the difference between B and V.

Now let N be the moon's mean motion referred to 1 as the unit of time, and $(N + \delta N)$ the moon's mean motion referred to $(1 + x)$ as the unit of time,

then $(N + \delta N)\ (1 + x) = N$,

$$\text{and } t\delta N = \frac{N}{n} \left\{ 0{\cdot}055871 \,.\, t - 0{\cdot}0000114955 \,.\, t^2 \right\}$$
$$= 0''{\cdot}747 \,.\, t - 1''{\cdot}54\left(\frac{t}{100}\right)^2.$$

But Hansen determined his mean motion of the moon so as to force an agreement between his theory and observations reduced with Bessel's unit 1; and his tables, therefore, represented the observations well for many years, whilst 1 was adopted as the unit of time; but directly the unit of time was changed by the adoption either of H or V, then the effects of the erroneous determination of the moon's mean motion by Hansen became apparent. The change of error in longitude of Hansen's Lunar Tables between 1864, when Le Verrier's Solar Tables were adopted in the *Nautical Almanac*, and 1880, amounts to more than 10″.

The effect of the change of unit is also shown in the comparison of Le Verrier's Solar Tables with observation, but of course only to about the thirteenth part of the amount shown by the Lunar Tables. The necessity of adopting some definite unit of time by fixing the constants in the expression for the longitude of the mean sun is insisted upon.

If $L_0 + n_0t + S_0t^2$ is the expression adopted for the longitude of the mean sun, the quantities L_0, n_0, S_0, must never be changed. The correction δL, which from time to time may appear necessary to obtain the mean longitude of the sun from the longitude of the mean sun must not be allowed to change the adopted values of L_0, n_0, and S_0. The true longitude of the sun will then

$$= L_0 + n_0t + S_0t^2 + \delta L + \text{periodic terms}.$$

It would appear that speculations respecting changes in the time of rotation of the earth on its axis are at least premature until the theories have been revised with a unit of time freed from changes of adopted constants which are at present inextricably mixed up with any effects which would result from a change in the time of rotation of the earth on its axis.

The longitude of the mean sun when properly investigated, differs from the mean longitude of the sun by a secular term—

$$0''{\cdot}3113\left(\frac{t}{100}\right)^2.$$

As this difference has been usually neglected in the determination of the sidereal time at mean moon, an error of about

$$13 \times 0''{\cdot}3113 \,.\, \left(\frac{t}{100}\right)^2, \text{ or } 4''\left(\frac{t}{100}\right)^2$$

has been thrown upon this secular acceleration of the moon's mean motion. This accounts for the difference between Adam's theoretical value, and that deduced from eclipse observations.

Chemical Society, May 3.—Dr. W. H. Perkin, president, in the chair.—The following papers were read:—On a new oxide of tellurium, by Dr. E. Divers and M. Shimosé. When the compound of sulphur trioxide and tellurium, discovered almost simultaneously by the authors and by Weber, is treated in a vacuum, sulphur dioxide is evolved and a new oxide of tellurium is formed containing one atom of tellurium to one atom of oxygen. The decomposition takes place between 180° and 230°. The oxide is black, and quite stable at ordinary temperatures in dry air. No compound of this monoxide has yet been prepared, but in its properties it is essentially different from a mixture of tellurium and dioxide.—On tellurium sulphoxide, by Dr. Divers and M. Shimosé. The authors prepared this compound by pouring sulphur trioxide on to tellurium finely powdered and dried. It was purified from sulphur trioxide by heating to 35° and exhausting with the Sprengel pump. It is a red amorphous solid, quite stable at ordinary temperatures in sealed tubes. When heated in a vacuum to 90° it is changed into a bright fawn coloured modification.—On a new reaction of tellurium compounds, by Dr. Divers and M. Shimosé. When sulphuric acid containing a small quantity of tellurium dioxide or sulphate in solution is poured into a hydrogen-generating apparatus, and the escaping hydrogen passed through a second portion of the telluretted sulphuric acid, a beautiful red colour, due to tellurium sulphoxide, is rapidly developed.—On a simple modification of the ordinary method for effecting the combustion of volatile liquids in Glaser's furnace with the open tube, by Watson Smith. The author causes the end of the combustion tube to project from the furnace, and volatilises the liquid by gently warming the current of gas with a Bunsen burner.—On the production of ammonia from the nitrogen of minerals, by G. Beilby. The author gives the results obtained with typical oil and coal shales when distilled (1) at a low red heat, (2) at a low red heat in a current of steam, (3) at a low red heat in a current of steam, the residual coke being afterwards subjected to the prolonged action of steam, so that a large portion of the coke is consumed and the nitrogen in it liberated as ammonia. Thus a sample of oil shale furnished by (1) 2·7 lbs. of nitrogen per ton as ammonia, by (2) 3·9 lbs., by (3) 12·0 lbs.—On the specific gravity of paraffin wax, solid, liquid, and in solution, by G. Beilby.

Zoological Society, May 1.—Prof. W. H. Flower, F.R.S., president, in the chair.—The Secretary read an extract from a letter addressed to him by Mr. W. L. Crowther, C.M.Z.S., respecting the possibility of obtaining living specimens of the Thylacine of Tasmania.—The Secretary exhibited, on behalf of Mr. H. Whitely, the skin of a Bird of Paradise (*Diphyllodes gulielmi*) from the Island of Waigiou, which was believed to be the second example of this rare species yet obtained.—The Secretary exhibited a set of Radde's international colour-scales, and explained the way in which it was intended to be used.—A

communication was read from Mr. F. Moore, F.Z.S., containing the second part of a monograph of the sections *Limnaina* and *Euplœina*, two groups of Diurnal Lepidoptera belonging to the subfamily *Euplœinæ*. The present paper contained the descriptions of many new genera and species belonging to the group *Euplœina*.—Mr. Alfred Tylor, F.Z.S., read a paper on the colouration of animals, showing that the character of the ornament or decoration differs in the two great divisions of the animal kingdom—the Invertebrata and Vertebrata. Mr. Tylor pointed out that the law of emphasis, well known in architecture, was, in his opinion, applicable to natural history, and showed that the prominent characters of the animal are picked out in colour in precisely the same manner whenever colour is present. He divided his subject into several sections, and exhibited illustrations of the more important families in coloured diagrams.—A communication was read from Dr. O. Boettger, of Frankfort-on-the-Main, containing the description of new species of land-shells of the genus *Clausilia* from the Levant, collected by Vice-Admiral Spratt, F.R.S.—Mr. W. F. Kirby gave an account of a small collection of Hymenopterous and Dipterous insects obtained in the Timor-Laut group of islands by Mr. H. O. Forbes.

Mathematical Society, May 10.—S. Roberts, F.R.S., vice-president, in the chair.—Prof. M. J. M. Hill, of the Mason College, Birmingham, was elected a member.—Prof. Cayley made a communication on Mr. Wilkinson's rectangular transformation.—Mr. Tucker read abstracts of papers by Prof. Genese, relations between the common points and common tangents of two conics; by Mr. W. R. W. Roberts, on the motion of a particle on the surface of an ellipsoid; and by Mr. R. A. Roberts, on unicursal twisted quartics, part ii.; he also made a communication on two concentric circles. The circles considered were a circle which the author proposes to call the "Triplicate-Ratio" (T.R.) circle and Brocard's circle. If through a point (P) within a triangle ABC (whose trilinear coordinates are $2a\Delta/\kappa$, $2b\Delta/\kappa$, $2c\Delta/\kappa$, where κ stands for $a^2+b^2+c^2$), straight lines DPE^1, EPF^1, FPD^1 be drawn, then the circle $DD^1EE^1FF^1$ is the T.R. circle. The origin of the name is due to the fact that the intercepts on the sides (DD^1, EE^1, FF^1) are equal to a^3/κ, b^3/κ, c^3/κ respectively. If $\lambda^2 = a^2b^2+b^2c^2+c^2a^2$ and $\mu = \lambda/\kappa$, then the triangles DEF, $D^1E^1F^1$, which are equal to one another, and are similar to ABC, have their sides $= \mu a$, μb, μc. The lengths D^1E, E^1F, F^1D are equal to abc/κ, so that the perimeter of the above-named hexagon is $(a^3+b^3+c^3+3abc)/\kappa$. Other curious properties were pointed out. If the angle BFD be denoted by ω, then $\cot\omega = \cot A + \cot B + \cot C$, and several other trigonometrical relations were indicated. If through A, B, C lines are drawn parallel to the sides of DEF, $D^1E^1F^1$, these by their intersections determine five of the points on Brocard's circle, the other two Brocard points being P and H (the centre of the circum-circle). Lastly the trilinear equations to the two circles were given, and it was shown that the two circles are concentric. The T.R. circle also divides each side into segments which are in the duplicate ratios of the sides.—The Rev. M. M. U. Wilkinson read a second paper on spherical functions.

Geological Society, April 25.—Mr. J. W. Hulke, F.R.S., president, in the chair.—Rev. William Franklen Evans, Ernest Hall Hedley, and Henry James Plowright were elected Fellows, and Dr. J. S. Newberry, of New York, a Foreign Member of the Society.—The following communications were read:—On the skull of *Megalosaurus*, by Prof. R. Owen, C.B., F.R.S. The specimens described in this communication were obtained by Edward Cleminshaw from the freestone of the Inferior Oolite near Sherborne (Dorset) from some blocks which had been quarried for building purposes. These were sent by him to the British Museum, where the remains have been developed. One block includes a great proportion of the right side of the facial part of the skull, the missing parts being the fore-end of the premaxillary, the suborbital end of the maxillary, and the upper hinder pointed termination of the same bone. Ten teeth are preserved in the maxillary bone. Another block contains the outer side of the right mandibular ramus with teeth and with some other fragments. In a third block is the anterior part of the left mandibular ramus with portions of the teeth. These remains were described in detail; and in conclusion the author discussed the bearing of these and other Megalosaurian remains upon our knowledge of the structure of that animal and its affinity to existing Reptilia, and criticised some of the evidence on which the relationship of the Dinosauria to birds is inferred, a relationship which he had suggested in 1841, but upon grounds which appeared to him to be more satisfactory.—Notes on the Bagshot sands, by Mr. H. W. Monckton, F.G.S.—Additional note on boulders of hornblende picrite near the western coast of Anglesey, by Prof. T. G. Bonney, F.R.S.

Institution of Civil Engineers, April 8.—Mr. Brunlees, president, in the chair.—The paper read was "On the Diamond Fields and Mines of South Africa."

EDINBURGH

Mathematical Society, May 11.—Mr. J. S. Mackay, F.R.S.E., president, in the chair.—Mr. D. Munn, F.R.S.E., gave an address on the geometry of the nine-point circle, and Dr. C. G. Knott, F.R.S.E., a paper on Newton's "Opticks."

BERLIN

Physical Society, April 30.—Dr. Pringsheim reported on his recently published measurements of the wave-lengths of the least refractive rays of the solar spectrum. In order to obtain them he used a radiometric torsion apparatus, similar to those used by Crookes, which carried a small mirror by which the revolution of the torsion-beam caused by the ray could be observed. The source of light were solar rays reflected into a dark room by a heliostat, first united in a focus by a concave mirror, then rendered parallel and directed upon a revolvable grating-mirror, which produced a whole series of spectra. The various divisions of the first spectrum were directed upon the torsion-apparatus by means of a slit, and it was noted up to what wave-length the mirror still performed part of a revolution. In order to exclude the visible rays of the second spectrum which were mixed with the infra-red ones of the first spectrum, and prevent their reaching the torsion-apparatus, Dr. Pringsheim cut them off partly by an iodine solution, partly by an ebonite plate according to Abney. The extreme limit of the spectrum where an effect was still observed was at the wave-length $\lambda = 0{\cdot}00152$mm.—Prof. Neesen reported upon a treatise entitled "On the Contractions of Volume as a Measure of Chemical Affinities," sent to the Society for publication in its *Transactions* by Herr Müller Erzbach of Bremen. He shows in a number of salts formed by selenic and chromic acids that in chemical combination a stronger contraction of volume corresponds to a greater chemical affinity, and is shown in the heat generated when the combination takes place; while in those salts which show a smaller contraction, acid and base are bound together by less powerful affinity.

THURSDAY, MAY 24, 1883

SCIENCE AND ART[1]

WE stated in our article last week that we should take an early opportunity of noticing some of the pictures in this year's Academy, with especial reference to the points which we then mentioned. The following notes are a fulfilment of that promise. It is to be understood that only those pictures which illustrate, either by their perfection or their defects, the points in question have been referred to. The pictures have been classified according to the particular class of natural phenomena which they portray.

SKY COLOUR

2. "Homewards," Wm. J. Monkhouse Rowe. Sky not zoned; impossible colour of clouds. Perhaps our word zoned requires some little explanation. When the sun is at such an altitude above the horizon that the blue rays are absorbed, and there begins to be colour on cloud and sky, then the sky at the same altitude is always of the same colour, and the colours gradually modulate from the warmest at bottom to the coolest at top. These remarks with regard to the sky have, of course, nothing whatever to do with the clouds, but whatever the colour of the clouds may be, and this will depend upon various conditions, any true clouds, however they may be coloured, shown on the picture at the same altitude, will be surrounded by the same sky colour, even if the intensity differs in consequence of different distances from the sun's place. For instance, if a painter chooses to put a bright green sky at 5° or 10° elevation on the right of his picture, and then paints a blue sky at the same elevation above the horizon on the left, he is showing something which is impossible: his picture is not perfectly zoned.

76. "Welbourne Hall, Yorkshire," H. A. Olivier. Sky well zoned, but its reflection from water too intense. Reflection will naturally lower the tone of the reflected light, but, all the same, this difference may not come out very strongly, for the reason that the reflection is most frequently and necessarily shown in a darker part of the picture, so that although by mere contrast the tone seems lowered, it will yet appear to be brighter than the tone seen in the region of more general illumination.

132. "To Pastures New," James Guthrie. Sky of impossible colour.

121. "Freshening," A. Harvey Moore. Sky and sea both admirable.

157. "Corrie, Isle of Arran," John MacWhirter, A. Sky admirable; water a little doubtful. It is also not level.

218. "The Dogana and the Island of San Giorgio, Venice," Frank Dillon. Sky colour and water reflection good.

233. "After Sundown," Frances R. Binns. Excellent in sky colour, but zoning might have been more perfect.

242. "Superstition," Everton Sainsbury. Good and bold sky colour, especially the red, but the sky is too much worked to resemble cloud.

246. "Autumn," A. Glendening, jun. Good, and forms of clouds quite excellent.

247. "The Forgotten Sheaf," F. S. Walker. Zoning gone wrong; green never rests on white, nor on gray.

269. "And the Unclean Spirits went out of the Swine," Briton Riviere, R.A. Bold and perfect sky and clouds.

297. "Windsor," Vicat Cole, R.A. Might have been more evenly zoned.

315. "A Mortally Wounded Bandit Chief Exhorting his Comrades to Return to an Honest Living," J. R. Herbert, R.A. There is no relation between the light, the colour of the sky, and that of the landscape.

327. "Grouse-driving on Bowes Moor, Yorkshire," George Earl. It is difficult to understand by what means the sky to the left is illuminated.

331. "Carting for Farmer Pengelly," J. C. Hook, R.A. Sky and clouds admirable; green on the cliff very striking.

371. "A Silent Pool," Fred. E. Bodkin. A slight change in the colour of the clouds would make this an admirable picture.

394. "November," E. A. Walton. Let us hope this is not true sky colour. Far too deep a green, and there is no reason why the clouds at the top of the picture should not be as intense in their lower portions as the mass of cumulus on the horizon.

398. "Ben Ray," H. W. B. Davis, R.A. There is not sufficient relation between the colour of the sky and the colour of the landscape. (Compare 702.)

700. "Trabacolo Unloading at the Custom House, Venice," Clara Montalba. The sky colour is wrong. There could have been no green where the artist has placed it.

702. "At Kinlochewe," H. W. B. Davis, R.A. (compare 398). In this case the sky is wedded to the landscape, and we have a perfect and harmonious whole beautifully luminous.

713. "A Summer Evening, Folkestone," W. Ayerst Ingram. Nearly perfect zoning of cloudless sky, but the reflection from the water has been a little too much toned down perhaps.

773. "Winnowing Gleanings," H. Gillard Glindoni. Sky and seascape both admirable.

826. "The Boundary of the Heath," J. C. Harrison. Careful study of sky. Bank of trees against it very effective.

793. "Rochester from the River," Charlie W. Wyllie. A pleasing picture—both sky and water good.

1438. "Leaving Labour," E. B. Stanley Montefiore. Impossible green sky.

1503. "Lost Sheep," Robert Page. It is a pity this artist takes the trouble to paint a sky, because it is evident he does not know the difference between sky and clouds.

1483. "A Spanish Aqueduct," Adrian Stokes. Note colour of sky and landscape and effect of heat under tropical sun.

CLOUDS

225. "On Solway Sands," Thomas Hope M'Lachlan. Blue clouds.

257. "Still Waters run Deep," George Chester. The clouds in this picture are hideous in form and impossible in colour.

339. "Night into Day," Vincent P. Yglesais. This may be a view in Mars. It is fortunately impossible here.

577. "Rye, Sussex," Leslie Thompson. A new kind

[1] Continued from p. 51.

of cloud is here represented, one resembling mashed potatoes.

602. "A Calm—Bay of Naples," F. W. Jackson. Good study.

1461. "Between the Showers," Henry Moore. Good study of clouds.

DISTANCE AND ATMOSPHERE

279. "Gathering the Flock," H. W. B. Davis, R.A. Perfect distance, toning carefully preserved, and the picture is free from the exaggeration which one so often laments. The illumination of the sheep is, however, too local.

321. "Highlands and Lowlands," William Linnell. Admirably managed distance.

479. "Light in the West: After Rain," Alfred W. Williams. The artist seems to have too strongly contrasted the peaks against the sky. The peaks though high are really distant, and hence there is atmosphere between us and them.

96. "Snowdon," Joseph Knight. Everything that could be desired.

255. "Llyn-yr-Adar on the Adder's Pool, Carnarvonshire," J. W. Oakes, A. This is the picture referred to at length in the preceding article. We repeat that it is a pity the author did not study the rainbow before he attempted to paint it.

843. "Spring Time at Tillietudlam Castle, Lanarkshire," David Murray. The effect of sunshine on grass is here carefully rendered, but there is a little too much colour in the delicate clouds in the centre of the picture.

SUNSETS

98. "Parting Day," B. W. Leader, A. Careful study, rifts admirably attempted, but the treatment of them is not quite perfect, especially on the right of the picture. As a rule the clouds must be lower down than they are here represented to give the effect sought to be rendered.

Note on Rifts.—These rifts, which have attracted the attention of Mr. Leader, are only possible when the air is very densely charged with aqueous vapour, for the reason that they are a projection upon the distant sky of a cylinder, less illuminated than the surrounding air, owing to the interposition of a cloud low down in the atmosphere. Now, as whatever the condition of the air may be it must obviously get more dense as the earth is approached; the lower the cloud the stronger will be the rift, and the more the cylinder of shadow is directed to the point overhead the more definite will be the rift, for the reason that along the line of sight the greatest distance will then be in shadow. We are really in such a case dealing with a partial eclipse of a long column of air, and as at any one place the conditions of the atmosphere at the same time will be almost, if not quite, identical, if rifts produced by clouds are shown on one side of the picture, the other side of the picture should show rifts produced in like manner. This we think is a point which Mr. Leader has very pardonably missed. The reflection of the clouds in the water is not quite true.

164. "Sunset Fires," John MacWhirter, A. This picture is spoiled because the artist has made no distinction between the colours of the sky and of the clouds.

399. "At Last!" Fred. C. Cotman. Sunset and water reflection; a beautiful picture.

1471. "An Autumn Evening," B. W. Leader, A. This is a very fair sunset sky, but a little too cool in colour, and the reflection in the water is not good. There is however a careful bit of painting in the way in which the top of the cumulus is reflected over the bridge.

MOONS, &c.

214. "Tipt with Eve's Latest Gleam of Burning Red," James S. Hill. It is quite impossible that such a moon should be at such a height at sunset, besides which the moon is more shapeless than she should look under the given cloud conditions.

232. "Too Late," Frank Dicksee, A. Everything about this picture when we leave the figures, with which we are not at present concerned, is wrong. We have an impossible moon in an impossible sky. The artist has attempted to paint the old moon in the new moon's arms, one of the most beautiful natural phenomena visible after sunset, but by a strange fatality almost every point where science could have assisted the artist has been neglected. As is known to many children, the appearance of the complete body of the moon on such an occasion as this, when only a very thin crescent is illuminated by the sun, depends upon the fact that the earth reflects light to the moon, hence the term "earth shine," the equivalent of "la lumière cendrée" of the French. Under these conditions we have in fact a thin crescent illuminated by direct sunlight, whilst the rest of the moon is illuminated by light reflected from the earth. One of the points of this earth illumination which Mr. Dicksee has entirely missed is this, that the earth-light must be equally distributed over the whole surface of the moon which it illuminates. Sunlight reflected from the earth to the moon, and then reflected back again from the moon to the earth, must be quite general in its action, and must equally light up each part of the lunar surface. Hence the absolutely equable illumination which is always seen, but which this picture fails to show. The fact that the old moon thus illuminated appears to rest in the new moon's arms depends upon irradiation, by the operation of which a thing very brilliantly illuminated looks larger than when it is dimly illuminated. That part of the moon, therefore, which shines by the brilliant light of the sun, appears to belong to a larger body than that part which receives its less brilliant illumination from the earth. This appearance is so obvious that it has given rise to the old world illustrations, in which the "old" moon is represented as in a boat, because in fact the two horns of the crescent moon extend beyond the old moon as we have said, and appear to form part of a larger circle. This point also Mr. Dicksee has entirely missed. What we have to say touching the colour of the sky is, that neither Mr. Dicksee, nor any one else, ever saw such a colour as he has painted to indicate the place of sunset. At such a height above the horizon a green colour is impossible, it must either be red, or yellow, or grey, according to the state of the atmosphere at the time. We have ventured to speak thus at length with reference to this picture, because we consider it a very typical case, and surely Mr. Dicksee, when he becomes acquainted with the facts to which we have drawn attention, and as to which there can, we believe, be no dispute, will regret that he should have disfigured his

picture by disregarding them. Had these things been correctly painted the picture would have been just as beautiful to the ignorant as it is at present, whilst it would have had the additional advantage of being also pleasing to look upon by those who can in its present form only regard it with regret. It may be said that these are simple matters. Be it so. Simple or not they are typical, and that is the point we wish to urge.

260. "The Ides of March," E. J. Poynter, R.A. The comet is admirably rendered, but does not the little lamp give out rather too much light?

697. "The Dawn of Night," Richard Whatly West. It is not easy to understand this picture, as the title of it is "The Dawn of Night"; but if we have the moon rising then the sky is far too dark.

807. "Can He Forget?" Edward H. Fahey. This artist is to be congratulated on his moon. He has painted it so that any one with a very simple calculation can determine that he is quite wrong. If the young lady asking the interesting question had had a crown in her hand, the coin would have covered the real moon. She herself would hardly cover the false one. So, to one who knows, it looks like Nadar's balloon without the netting being inflated. Further, each part of the moon when she rises is generally under the same atmospheric conditions, so that such a variation in its illumination as is here shown is almost impossible unless a definite cloud is darkening its surface, and no such cloud is here to be seen.

888. "Moonlight," Robert Jobling. It would have been better if in this moonlight scene the artist had discriminated more between the clouds and their background the sky.

546. "Moonlight Bay, Milford Haven," F. W. Meyer. Very careful study of moonlight.

Water

28. "Catching a Mermaid," J. C. Hook, R.A. Colour and forms of waves, and swirl and dash on rocks, good.

133. "Wind against Tide: Rillage Point, Ilfracombe," J. Geo. Naish. Sea and sky excellent in the distance; water a little weak in foreground, both as to colour and forms of waves.

202. "Oyster Dredgers," C. Napier Henry. Water in this picture is not level.

281. "High Tide at Kynance, Cornwall," Sidney R. Percy. The wave at the left is being forced back by nothing, and is altogether too solid.

282. "A Rising Gale: Dunbar Sands, Padstow, Cornwall," Walter J. Shaw. Very bold low front view of breaking waves. Reflection good.

301. "The Gull Rock: off Kynance Cove, Cornwall," Edmund Gill. Colour and form of water quite admirable.

467. "A Travelling Cobbler," Joseph Henderson. Colour of water very true to nature. The distant land deserved more careful painting.

498. "The Last of the Crew," Briton Riviere, R.A. This ice is a careful study of form and colour.

495. "A Fisherman's Garden," Theodore Hines. Water not level.

711. "The Sad Sea Wave," John Francis Faed. Colour of water very brilliant.

695. "Lobster Fishers," Colin Hunter. Form of waves very careful study.

778. "A Haven," C. E. Holloway. Note colour of water and form of waves. The artist should say where this Haven is, that it may be avoided by all who love the beautiful.

809. "Welsh Dragons," John Brett, A. Note colour of water and rocks. Mr. Brett is again quite perfect in his treatment, but we rather doubt the colour of some of the cumuli that float over the sea, and also their sharp darkened boundaries.

145. "Adrift," R. C. Leslie. An admirable study of water, far too good to be skied.

Reflection

36. "Love Lightens Toil," J. C. Hook, R.A. The reflection from the water has not been carefully studied. Does not the green of the grass come too low down to the water? The water, too, is not level. Current indicated.

86. "A Quiet Noon," Peter Graham, R.A. The reflection of the clouds from water is not quite in accordance with their form; the clouds themselves are admirable.

83. "The Enchanted Lake," Albert Goodwin. Careful study of reflection. The artist has left out what most artists would incontinently have put in, but there are several blunders; for instance, it is the under side of the umbrella which should have been reflected, and not the upper one, and the colours of the objects reflected are too entirely lost, as if the reflection were from the bottom of the enchanted lake instead of from its surface. The artist's idea has evidently been that there have been two transmissions of the light through the water, in consequence of which its original colour has been lost. This cannot have been so.

123. "On the Marshes," Percy Belgrave. The ordinary laws of reflection do not seem to apply in this case.

162. "Loch Scavaig, Isle of Skye," Sydney R. Percy. Even if the moon had not been veiled by a cloud we could not get this effect, nor with such rough water would the wake alone have been so illuminated; we should have had side reflections as well.

168. "Loch Alsh," Colin B. Philip. Good; distance and water reflection carefully managed

356. "Among the Trawlers, Tarbert, Loch Fyne," Andrew Black. Reflection from water very admirably managed.

508. "Green Pastures and Still Waters," B. W. Leader, A. The reflected images of the trees in the distance are about one and a half times as long as the trees themselves. Still water does not magnify the height of objects when they are reflected in it. One of the branches of the tree to the left has also considerably suffered by the reflecting process.

648. "A North Country Stream," Alfred W. Hunt. Very perfect study of water, the light reflected by the surface being mingled with that coming from the bottom.

688. "Willows Whiten, Aspens Quiver," Keeley Halswelle. Admirable landscape and water, but the colour and shapes of the clouds are unsatisfactory, and the picture would be better without them.

1509. "A Pebbled Shore," Colin Hunter. Note the way in which the cumuli are reflected from the waves beneath them. Glorious picture.

1493. "Toil, Glitter, Grime, and Wealth on a Flowing Tide," W. L. Wyllie. An admirable picture, but we question whether the artist is justified in getting such a brilliant reflection from the surface of the water to the

left, where the sky as indicated does not appear to be a very luminous one.

142. ". . . these Yellow Sands," John Brett, A. In this admirable picture, in which the sea and sky are quite perfect, Mr. Brett has attempted some difficult effects. More transparent water has never been seen on a canvas, and the colour of the yellow sand at its bottom is beautifully mingled with the light reflected from its surface.

626. "Sounding for Shallows at Low Nile," Tristram Ellis. A bold attempt at reflection in the Nile water, but, as a matter of fact, the real colour is not so entirely subordinated by reflection.

SNOWSTORMS

764. "The Joyless Winter Day," Joseph Farquharson. The storm must have been very considerate to the artist. In spite of the driving blast there is not a single snowflake to be seen in the first twenty yards.

THE LIVING ORGANISMS OF THE ATMOSPHERE

Les Organismes vivants de l'Atmosphère. Par M. P. Miquel, Docteur ès Sciences et Docteur en Médecine, Chef du Service micrographique à l'Observatoire de Montsouris. (Paris: Gauthier-Villars, 1883.)

PLUS occidit aer quam gladius, such is the main idea contained and explained in M. Miquel's very able and interesting book. If the modern theories are true, it must be certainly conceded that although the sword and gun are very murderous tools, air is yet more so. But on the other hand one may say of our atmosphere's murderous propensities what a French writer said when he was told that coffee was a poison: "Well, it may be a poison to be sure, but it must be a very slow one; I have been indulging in it for over fifty years." In fact, if Voltaire and many other men took too much of it, it began to tell on them only very late. Taking it for granted that coffee is murderous, it must be also granted that it is not always so. Such is also the case of the atmosphere we live in.

The influence of infinitely small organisms contained in the air and water, as well as in the body of man and animals, can no longer be denied, at least, in a general manner. Certainly much remains to be done to bring the Microbe Theory to the point it must attain; many inconsistencies and discrepancies yet interfere with its general harmony; but Davaine's and Pasteur's experiments and discoveries have certainly opened new ways in science.

Now that it is granted that the organisms alluded to are to be found and may thrive in the air, it is interesting to know what these are, how abundantly they may be found in the atmosphere, and by what means they may be captured and experimented upon. To these important questions M. Miquel answers in a very precise and interesting manner.

It is not a difficult thing to detect the corpuscles contained in the atmosphere; a mere sunbeam in a room shows hundreds of them dancing in the light. But it is less easy to ascertain the nature of these little atoms; great skill is required to do that. Some are vegetable, some are mineral, some are animal.

M. G. Tissandier has established that a great quantity of mineral atoms is contained in the atmosphere; the most interesting of these are meteoric iron melted into the form of little globules. Some infusoria are also to be found, but bits of wool and silk, pollen and spores are more abundant. As one may easily believe, all these corpuscles are less abundant in the atmosphere after a fall of rain. For instance, M. Tissandier finds in a cubic metre of air 0·023 gramme of dust after a rainless week; 0·006 gramme the day after a heavy rain.

The description given by M. Miquel of the numerous instruments contrived by himself and by others to collect the corpuscles contained in the air is good and interesting, but is not easily condensed. Another very important chapter of this book is that concerning the nature and origin of the aërial corpuscles among which pollen, flour, and spores are most abundant. For instance, the number of spores to be found in a cubic metre of air is about 14,200. But this number changes very much according to the season. In winter the mean number is 6200; in spring, it is 13,000; in summer, 28,000; in autumn, 9800. The reason of these variations is easy to understand.

However abundant spores and pollen, woollen and silk threads may be in the air, that is a question of little importance when compared with that of the presence of bacteria in the atmosphere. Bacteria are to be found, often in great quantity, in the air. Generally speaking, according to M. Miquel's experiments and observations, bacteria are more abundant when the weather is dry; the reverse is to be observed concerning spores of inferior cryptogams. The direction of the prevailing wind has much to do with the number of bacteria found in the air. M. Miquel shows, by means of a diagram, how the air having passed through part of Paris, before coming to the Montsouris Observatory, contains more bacteria than that which passed only over the suburbs and country around the town. South winds bring from 42 to 77 bacteria to a cubic metre of air; northern ones bring from 108 to 152. Other experiments give the same results. M. Miquel draws from his numerous experiments the conclusion that the air in Paris contains nine or ten times more bacteria than does that outside of the fortifications or close to them. For instance, in the Rue de Rivoli, M. Miquel finds an average number of 760 bacteria in autumn, 410 in winter, 940 in spring, and 920 in summer; that is, a mean annual number of 750 bacteria per cubic metre of air. At Montsouris the mean annual number is 75. The minimum number found by M. Miquel is 45 (winter 1882); the maximum is 3000 (summer 1881) bacteria per cubic metre.

In hospitals, the air contains a much greater quantity of bacteria, as might be expected; the cubic metre contains an average of five or six thousand! In some cases M. Miquel has found ten, even sixteen, twenty-one, and *twenty-eight thousand* bacteria per cubic metre of air. These last numbers are stupendous.

These bacteria in the air, liable every moment to penetrate into our lungs and body, are of many sorts. Some are spherical,—the *sphero-bacteria*; they generally have no power of locomotion; some are coloured red or yellow. M. Miquel remarks that although some of these bacteria must exert a pathogenetic action, he has not been able to produce any disease in ani-

mals by means of these organisms. It may be that the atmosphere kills these bacteria, it may be that the animals experimented upon were not liable to catch the disease; at all events it would seem that no pathogenetic bacteria are to be found in the air. This is a very important conclusion, but it is not yet sufficiently supported by facts. How could scarlet fever, measles, and other diseases be brought by a physician from a patient to a healthy person if the bacteria could not resist the action of the air for some time?

Other bacteria present a more elongated shape: they are called *bactéries en batonnets.* They generally move about, sometimes very slowly, sometimes with great rapidity, in various manners, when they are allowed to remain in a suitable liquid. M. Miquel has remarked that one of these bacteria converts sulphur into hydrosulphuric acid in a very energetic manner; together with another similar bacterium it is the principal agent that converts urine into sulphuret of ammonia. M. Miquel cannot say exactly as to the presence of pathogenetic bacteria in the atmosphere, nor especially as to their precise nature and *modus faciendi.*

Bacilli are also to be found in the atmosphere; they may be long or short; the less they move about the longer they become. One of these bacilli resembles very much the *Bacillus amylobacter* (van Tieghem). Another one seems pathogenetic; it brings on, in animals, a phlegmon that generally terminates—as is the custom of most phlegmons—in suppuration. Of course many other pathogenetic bacilli perhaps exist in the atmosphere, but that question has not been specially discussed by M. Miquel. He shows very well how considerable an influence the rainfall exerts on the number of the bacteria contained in the air. Temperature has little to do with this as diagrams show; rain on the contrary has a great effect. As soon as the weather becomes dry the number of the bacteria increases; when it is rainy this number falls rapidly. This result is one of the most important among those M. Miquel has attained, inasmuch as this *savant* shows that rainy periods are those during which the bacteria multiply.

If the number of these organisms is considerable in the air we breathe every day, one thing must however console us in some degree. If these bacteria are murderous, they are somewhat like the coffee; they kill very slowly in most cases. Many of them must each day come into our lungs and body, and yet we feel none the worse for it generally. This does not mean that they are not dangerous; it means only that they are not always able to act a dangerous part. For what reason, we know not yet. Typhoid fever, cholera, yellow fever, measles, scarlet fever, and a great many other diseases are contagious; but all persons who live with patients suffering from either of these diseases do not catch them. Most doctors and medical students do not catch any contagious disease in the hospitals, and yet they doubt not the nature and danger of these diseases.

Whatever opinion one may entertain as to the Microbe Theory, it must be admitted that M. Miquel's book is exceedingly useful and well arranged. M. Miquel understands the matter thoroughly, and his book will certainly be much read abroad, as it has been in France.

HENRY DE VARIGNY

ANIMAL TECHNOLOGY

Animal Technology as Applied to the Domestic Cat. An Introduction to Human, Veterinary, and Comparative Anatomy. By Burt G. Wilder, B.S., M.D., and Simon H. Gage, B.S. (New York and Chicago: A. S. Barnes and Co., 1882.)

MESSRS. BURT WILDER AND GAGE are not the first anatomists to employ the domestic cat as an introduction to the study of vertebrate anatomy. In 1881 Mr. St. George Mivart published an elaborate treatise on the Cat, as a type for examination and comparison with other vertebrates; and as far back as 1845 M. Straus-Durckheim issued his well-known work in the French language on this animal.

The book now before us differs however in its scope and mode of treatment from its English predecessor. It is not like Mr. Mivart's, a systematic treatise on the anatomy of the cat, both macroscopic and microscopic, with chapters on its development, psychology, specific forms, geographical distribution, &c. But it is a practical treatise written with the object of instructing the student in the methods of dissecting and displaying the structure of this animal.

As preliminary to the anatomical description, the authors have written some short chapters on the instruments employed in dissecting, the modes of using them, the methods of injecting, and the preparation and preservation of anatomical specimens, so as to justify the title of Anatomical Technology given to the book. We would especially direct attention to the sections on the maceration of bones and the preparation of skeletons as furnishing the young anatomist with useful hints on these subjects.

Those who are familiar with the papers on Anatomical Nomenclature by Prof. Wilder in the American Journal *Science*, and elsewhere, will not be surprised to find that he has in this work again enunciated his views on Terminology, and adopted many but little used, as well as new terms in his descriptions. There can be no doubt that the terms used in anatomical description in many instances would be improved by being altered. No one who is engaged in the comparative study of the anatomy of the human body, with that of other vertebrates, but must constantly feel a difficulty in the use of the terms employed to express position. He has ever to keep in mind that a surface which is superior in man is anterior in any other vertebrate, and that a surface which is posterior in man is superior in vertebrates generally. Hence such terms as dorsal and ventral, cephalic and caudal, are much to be preferred to express corresponding surfaces throughout the vertebrata, whatever may be their direction, than posterior, anterior, inferior, superior. If indeed the recommendations made by the Edinburgh anatomist, Dr. Barclay, in the early part of this century, had been attended to, then anatomical description would by this time have been on a much more satisfactory basis than it is. The delay and difficulty in effecting the necessary reforms are largely due to the works on human anatomy having been for the most part written by men, who are specialists in that department only, and have not had a wide and philosophical training in the whole subject. The introduction, however, of biological study into

the scheme of a general education, and the publication of such books, as the one now before us, as guides to a practical knowledge of the structure of animals, will break up the conservative instincts of the purely human anatomists, and will lead in time to the adoption of a more scientific nomenclature.

To turn now to the descriptive part of this book. The impression we have derived from its perusal leads us to say that it is well adapted to the purpose for which it has been written. The authors have evidently studied the anatomy of the cat, not from the dissection of a single animal, but from numerous specimens. The methods of displaying structure, and preserving the parts for future observation and study are workmanlike and practical. The descriptions are clear and concise. Though at times terms are employed, such as ectal for external, ental for internal, trochiter for the great tuberosity of the humerus, and trochin for the lesser tuberosity, which are novel, and at first require a little thought to gather their meaning, they soon become familiar, and without doubt conduce to give clearness and accuracy to the description.

We ought not to omit to say that, as preliminary to the description of the cat's brain, the authors give an account of the dissection of the brain of the frog and the Menobranchus.

The work is illustrated with 130 figures in the text, and with four lithographed plates of the brain of the cat. The plates are neatly executed; but the figures in the text are in many cases coarse and inartistic. Surely in the United States, where the art of engraving on wood, as is shown in the illustrations to Scribner's and other monthly magazines, has attained such a high order of excellence, the authors ought to have been able to procure a draughtsman and woodcutter who could represent muscles, more like nature, than is given in say Figs. 66, 67, and 72.

OUR BOOK SHELF

Magyarország Asványai, Különös tekintettel termöhelyeik megállapitására. (*The Minerals of Hungary, with Special Regard to the Determination of their Occurrences.*) By Michael Tóth, S.J., Professor at the Gymnasium, Kalocsa. (Budapest, 1882.)

WE have here a contribution to science which reaches us from the far east of Europe, from Hungary. The author has aimed at nothing less than to give a complete catalogue of all the minerals that occur in that country, noting the exact place of the occurrence of each, and adding such statistical and other information as may enable the reader to form a judgment as to the economic value of the subject of the article. Special attention is given to such minerals as are of recent discovery or of such importance as to be likely to affect the future history of the district in which they are found.

Prof. Tóth is, we believe, the first writer who has attempted a complete account of the minerals of Hungary. His work would have been more widely useful had he seen fit to employ some language that is more widely known than his native Hungarian. But in the case of a work like this, which consists largely of names of places and of those technical names of species which are common to all the civilised world, the unfamiliar tongue does not render the book altogether useless. The author would seem to have looked forward to his work being used in England, for he has prefixed an English title-page, and frequently refers to the collections in the British Museum and the Museum of Practical Geology.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*

[*The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to insure the appearance even of communications containing interesting and novel facts.*]

Natural Selection and Natural Theology

THE amicable discussion between Dr. Romanes and myself, "endeavouring to help in determining the true position of an important question," has now (in NATURE, vol. xxvii. p. 527) reached a critical point, one seemingly capable of settlement by scientific inquiry, and upon which a brief note may be pertinent.

I take Dr. Romanes now to agree with me that the physical distinction of the less fit organisms, or, more generally, that the action of the environment, is not in a proper sense the cause of the advantageous variations of surviving organisms; also that natural selection does not explain and has no call to explain the cause of variation. As to this, he says, the theory merely supposes that variations *of all kinds and in all directions* are constantly taking place, and that natural selection seizes upon the more advantageous. Now if variation in animals and plants is lawless, of all kinds and in all directions, then no doubt the theory of natural selection may be "the substitute of the theory of special design," so as to efface that evidence of underlying intelligence which innumerable and otherwise inexplicable adaptations of means to ends in nature was thought to furnish. If it is not so, then the substitute utterly fails. For omnifarious and purely casual variation is essential to it in this regard. F y is it said that "the theory merely supposes" this. For omnifarious variation is no fact of observation, nor a demonstrable or, in my opinion, even a warrantable inference from observed facts. It is merely an hypothesis, to be tried by observation and experiment. I am curious to know how far the observations and impressions of the most experienced naturalists and cultivators conform to my own, which favour the idea that variations occur, in every degree indeed, but along comparatively few lines. That the investigator of any flora or fauna should so conclude as to actual and accomplished variation, is natural, but may go for little, the theory of course supposing that numberless non-occurring forms have failed in the struggle and disappeared. But there is no evidence that all sorts of varieties ever appeared or tended to appear, and there is a musty maxim about "*de non apparentibus et de non existentibus*" which is not devoid of application.

Moreover, as to the vegetable kingdom, it would seem that this question of omnifarious variation may be tested in the seed-bed and the nursery, from which Darwin took the idea and the term of natural selection. These indeed are actual experiments—very numerous and extensive—for the testing of incipient variation. If experienced nurserymen, gardeners, and others who raise plants from seed in a large way, usually with eyes watchful for variation, would give their testimony in this regard, they might materially contribute to the settlement of an interesting question.

We need not hold Dr. Romanes to the terms of his fundamental supposition, "that variations of all kinds and in all directions are constantly taking place." He probably means only that incipient variations are wholly vague and irrespective of ends—are as likely to occur in the direction of unfitness as of eventual fitness to the environment and to use, the divinity that shapes the ends—if ends there be—acting only through the surroundings. And we all understand that the particulars in which progeny differs from parent are potential in the germ, or in the cells of which the germ consists, and therefore wholly beyond observation. The upshot is, that, so far as observation extends, it does not warrant the supposition of omnifarious and aimless variation; and the speculative assumption of it appears to have no scientific value.

ASA GRAY

The Fauna and Flora of the Keeling Islands, Indian Ocean

I HAVE only recently been able to obtain my copy of Mr. Wallace's "Island Life," in which I find an estimate of the fauna and flora of the Keeling Atoll in the South Indian Ocean. I had the fortune to visit that outlying spot in the year 1879,

and made a collection both of its plants and of its animal life. With the exception of my birds and a few of the insects, my collections were destroyed by sea water, so that it is now impossible for me to give a definite list, but I may note that rats were in such numbers as to have become almost a plague. A goodly herd of introduced *Rusas*, a cross between the Sumatran (*C. equinus*) and Javan (*C. Hippelaphus*) species, were in excellent condition, and were living wild on Direction Island, where also pigs were living in the same state. Among birds, the *Gallus bangkiva* (introduced) was in considerable numbers; I saw also the nest of the *Ploceus hypoxanthus*, which comes, not every year, but very often to breed there, but the progeny seems either to die or to return to Java (?). I did not see the snipe, but of the *Rallus philippinus* I got several specimens. Egrets, blue and white, abounded and rested on the high trees on some of the islands. Lizards of several species are now found on most of the islands in large numbers. Of insects the number of species is very considerable. Coleoptera were represented by *Melolonthidæ*, *Cetoniidæ*, *Carabidæ*, *Elateridæ*, *Chrysomelidæ*, but as I have not my journals of that date by me, I cannot recall other families nor state the number of genera represented. Of Hemiptera I caught a good many species, mostly of small size. Many species of ants were observed. Neuroptera are represented, unfortunately, by the *termite*, introduced some years ago in furniture, it is said, but it occurs now on every islet of the group in myriads. I am told that during the cyclone of a few years ago, the whole surface of the sea was covered with the mangled bodies of dragon-flies for miles out to sea, but that since then very few have been seen. Of Lepidoptera I caught many species both diurnal and nocturnal, some very handsome, of which I sent a small collection to London in 1879. The Atlas Moth is rather common. Orthoptera were represented by the ubiquitous cockroach, and a few *Acridiidæ*.

Mr. Ross told me that on several occasions the large fruit bat, called the flying fox, has reached the islands, and once a pair arrived together, but died, from exhaustion apparently, soon after arrival. Under favourable circumstances, as in the case of an unusually strong pair, these may yet become inhabitants of the islets.

There are, I believe, considerable additions to the flora since Mr. Darwin's visit. It is only within recent years that the islands have become so greatly covered with cocoanut plants. Their original vegetation consisted principally of "iron wood" (sideroxylon ?) and other trees, and of low shrubs. These were nearly all burned out by accidental fires, one of which burned for three months. HENRY O. FORBES

Fatunaba, Timor Dilly, January 21

"Festooned" or "Pocky" Clouds (Mammato-Cumulus)

UNDER one of these names letters have appeared at different times in NATURE, notably on October 19, 1871. These were followed by a paper read before the Meteorological Society by Mr. R. H. Scott in February, 1872, in which he collects all the observations which had then been recorded, and the theories which had been propounded to explain them.

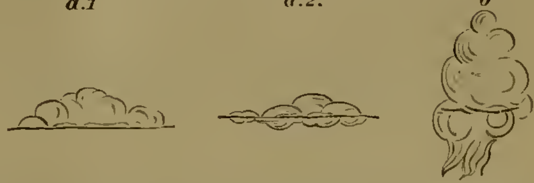
For several years I have been watching this kind of cloud, and I think that its formation is capable of a very simple explanation, partially in agreement with that suggested by Mr. Jevons in the earliest notice of these clouds (*Phil. Mag.*, July, 1857). The name is applied to a peculiar festooned appearance sometimes seen below cumulus and stratus clouds. In Orkney Mr. Clouston has found that it is usually followed by a severe gale; but in Lancashire, where the festoons are called "rain-balls," it is only considered a sign of rain. Other observers in the tropics have also seen it with thunderstorms, and not necessarily with wind. In this country I have observed it both in heavy gales and also in an ordinary summer thunderstorm. The method by which I have endeavoured to discover its origin has been to try and trace its life-history; that is to say, to follow its growth from other forms of cloud and to watch the forms into which it develops.

On one point almost all observers are agreed, that the festoons are frequently seen just before a cloud begins to break up. The first time that I was fairly able to trace the formation of the cloud was one summer evening in London, when towards sunset a flat-based cumulus, like that marked *a* 1 in the figure, suddenly became festooned at the base and diminished on the top, as marked *a* 2 in the figure. A few minutes afterwards the whole cloud evaporated. The succeeding night was fine. The explanation which immediately suggested itself was that the ascentional current which had formed the flat-based cumulus had suddenly failed, and that the festoons were simply the masses of vapour falling downwards for want of support.

Another very striking case is marked *b* in the figure, and was observed before a shower. Here a detached cumulus was observed to form first festoons, and then they in turn degenerated into raggy cloud, the whole disappearing very shortly, but was quickly followed by fresh rain-bearing clouds. The impression which the whole conveyed to me was that the festoons were formed by a sudden drop of the cloud, and that the "rag" was produced when the drop was less sudden. The appearance of the "rag" is not very well rendered in the diagram, but it is very difficult to delineate clouds by any engraving.

These are two typical cases of many which I have observed, and always with the same result—that the constant condition necessary for the formation of festoons was the sudden failure of an ascentional current of air. If so, the explanation of its prognostic value is very simple. Before many squalls or showers we are all familiar with the short, abortive gusts which so frequently precede them. Now we have only to assume that the ascentional uptake in front of the main body of the shower is as unsteady as the surface wind, and we have at once all the conditions of the formation of festoons. Almost all observers agree that they are usually formed at the edges of cloud masses. In the case of rain or thunder they ordinarily appear just before or after the rain; but in the case of a gale following some time afterwards, as observed by Mr. Clouston, the festoon must have been formed by some local squall or shower which bore some

a.1 *a*.2. *b*



relation to the disturbed weather which produced the gale. I once saw festoons in the west of Scotland during the hardest gale I have ever seen in this country. They were formed on the outskirts of a north-westerly squall.

Allied to festooned cumulus we may mention festooned stratus and festooned cirrus. The former is quite common in London during the summer, associated with showers or thunderstorms, while the latter is rare. In both the same idea seems to hold good as for cumulus, that they are formed by the sudden failure of the current, whatever it may be, that forms the stratus or cirrus.

It might appear, at first sight, that a uniform stratus could not fall in lumps; but however uniform it may seem, viewed from below, there is probably no such thing as a uniform stratum of cloud. Some portions are always denser, or composed of larger drops, and these, falling first, give the "pocky" appearance. In many simple cases, which I have been able to follow, there often seems to be a rough correspondence between bosses on the upper surface and festoons on the lower. In *a* 2 there is an unsuccessful attempt to depict such a case, which is drawn from nature.

The name of "festooned cloud" has been objected to as suggesting a lengthways arrangement of vapour, like the cloud called "rolled cumulus," with which it has probably nothing in common. Mr. Clement Ley has proposed the name of "tubercled cloud" as more applicable. Prof. Poey, who has also studied this cloud, has proposed the name of "globo-cumulus."

The general conclusion then, is that festoons are caused by a sudden failure of an ascentional current associated with showers or squalls, but whether they portend rain or wind depends on the circumstances under which they are observed.

21, Chapel Street, S.W., April 27 RALPH ABERCROMBY

The Sacred Tree of Kum-bum

PERHAPS the following statement may throw a little light on what was the tree seen by the Abbé Huc:—

On his voyage home from China the Abbé touched at Ceylon. This must have been in 1852 or 1853, as far as I can recollect. I was invited to meet him at breakfast, at the house of my kind

friend, Sir Charles Macarthy, then Colonial Secretary, my zoological and botanical tastes being well known to the latter.

The conversation turning on plants, the Abbé described a wonderful tree which he had seen, on the leaves of which were impressed thousands of likenesses of Buddha. Nothing was said about "Thibetan characters," nor did he lead us to suppose it grew larger than an ordinary cinnamon-tree (*not bush*), as it grows wild. His description was so detailed that, in spite of the florid language of a French traveller, I at once recognised a plant which grew not uncommonly in our gardens, the leaves of which were often placed in the finger-glasses after repasts, as on being crushed, they imparted a delicious fragrance to the hands. Looking up and catching the eye of our hostess, in which lurked an amused smile, I made the motions of dipping hands in a finger-glass. She instantly caught my meaning, whispered her instructions to the servant behind her chair, and each finger-glass —which useful adjunct to a meal was shortly after placed on the table—contained a leaf or two of what we used to call by a variety of names, such as the "profile laurel," or "figure laurel," or "face laurel."

The face of the Abbé was a picture to behold. "But here it is!" he exclaimed. "Where did this come from?" We then explained that it grew not a dozen yards from where he sat, to his great astonishment, and I fancied not a little chagrin, that his wonderful plant should be so well known and common.

The plant is, I believe a *laurel.* It has flashed across me that it *may be* a *citron*, but the plant is so well known in Ceylon, that if your contributor, Mr. W. T. Thiselton Dyer, wishes to ascertain its name, he has but to write a line to the Director of the Botanical Gardens, Peradenia, who will at once recognise it. The leaves are broad and pointed, shaped in fact somewhat like the cinnamon. Down each side of the midrib, extending along the veinlets (I write from memory, remember) are patches of pale greenish-yellow, much lighter than the ground-colour of the leaf. These take innumerable fantastic, face-like shapes— always profile—and with the aid of a pin, or point of a dessert-fork, we, in

"Those merry days,
The merry days, when we were young,"

used to put in an eye, and amuse ourselves in trying to find likenesses of our friends and acquaintances. It was a source of much fun among the young people.

The events of that morning were, from a variety of circumstances, deeply impressed on my memory, and I am positive that *then* nothing was said about "Thibetan characters" on the leaves or on the bark, nor of the *great size* of the tree, and the Abbé distinctly recognised the leaves as identical with those he had seen. You will perceive he calls it the "Tree of the Ten Tnou-and *Images*" (the italics are mine). This name would well apply to the "profile laurel," for no two faces are ever alike, but does not include *characters.*

Whether the size of the tree and the "Thibetan characters" grew (in the Abbé's brain?) after he left Ceylon, I do not know. The "real article" seems to have vanished. A bungling attempt to deceive by etching in lilac leaves could easily be detected, but "travellers see strange things"! E. L. LAYARD

Brit. Consulate, Noumea, New Caledonia, March 5

Sheet-lightning

THE correspondence on this subject (NATURE, vol. xxviii. pp. 4 and 54) can scarcely be said to contribute anything in support of the statement that sheet-lightning and the so-called summer or heat-lightning, are nothing else than the reflection of, or the illumination produced by, distant electrical discharges. The table given in the review (NATURE, vol. xxvii. p. 576) is not a record of instances of sheet-lightning, but only the number of hours, sorted according to the twenty-four hours of the day, in which sheet-lightning or heat-lightning was observed at Oxford during the twenty-four years ending 1876. In constructing the table, all those hours were excluded in which thunder was heard, and also the hour immediately preceding and following the hour of occurrence of thunder. Only those hours, therefore, were included during which any thunder that may have accompanied the lightning was at some distance from Oxford.

It follows simply as a matter of statistics that, if all cases of sheet lightning are nothing else but the illumination produced by distant electrical discharges, the curve of thunder and the curve of sheet-lightning and heat-lightning should be approximately parallel to each other after darkness has fairly set in. The Oxford observations show that such is not the case. To make this quite clear we give the results for August only :—

	Thunder.	Lightning.
8-9 p.m.	5	0
9-10 ,,	3	3
10-11 ,,	4	6
11-mid.	3	14
Mid.-1 a.m.	2	14
1-2 ,,	2	12
2-3 ,,	1	4
3-4 ,,	0	3

These two sets of figures from 8 p.m. to 4 a.m. furnish two curves quite distinct from each other; and the difference is not to be explained by the degree of facility for recording the observations afforded by each separate hour. It may be added that a similar result is obtained from electrical manifestations in other parts of the globe during the summer months. It is from these facts that it was concluded that no inconsiderable number of the cases of sheet-lightning and heat-lightning are not illuminations produced by distant electrical discharges, but, as suggested by Loomis, are rather to be considered as due to the escape of the electricity of the clouds in flashes so feeble that they produce no audible sound, and they occur when the air being very moist offers just sufficient resistance to the electricity to develop a feeble spark. THE REVIEWER

Solar Halo

THE following, taken from vol. i. *Philosophical Transactions*, p. 219, may interest your readers, as the phenomenon appears to coincide almost exactly with the one recorded in NATURE, vol. xxviii. p. 30. I omit the illustration, though it corresponds almost exactly with the one in NATURE, except that there were mock suns.

"An account of four suns, which very lately appear'd in France, published in the French *Journal des Sçavans* of May 10, 1666 :—

"'The 9th of April of this present year, about half an hour past nine, there appear'd three circles in the sky. *One* of them was very great, a little interrupted and white everywhere, without the mixture of any other colour. It passed through the midst of the sun's *disk*, and was parallel to the *horizon*. Its *diameter* was above a hundred degrees, and its *center* not far from the *zenith*.

"'The *second* was much less, and defective in some places, having the colours of a rainbow, especially in that part which was within the great circle. It had the true sun for its center.

"'The *third* was less than the first, but greater than the second, it was not entire, but only an arch or portion of a circle whose center was far distant from that of the sun, and whose circumference did by its middle join to that of the least circle, intersecting the greatest circle by its two extreams. In this circle were discerned also the colours of a rainbow, but they were not so strong as those of the *second*.

"'At the place where the circumference of this third circle did close with that of the *second*, there was a great brightness of rainbow colours mixt together. And at the two extremities where this *second* circle intersected the *first*, appear'd two parhelias or mock suns,' &c., &c."

In a note to this account it is stated that "Five suns appear'd the 29 March, A., 1629, at Rome between 2 or 3 of the clock in the afternoon." In the illustration given we find two circles similar to those given in NATURE. It seems that two of these suns "which were in the intersection of two circles, appear'd in that of a circle, which passed through the sun's diske, with another, that was concentrick to the sun."

The phenomenon of last week was minus the parhelia; can any reason be given for this? THOS. WARD

Northwich, May 15

IN reply to Mr. Mott's query (p. 30) I beg to say that I measured the halo with a sextant as carefully as possible, and made the semidiameter 25°. [Another halo occurring on the 13th measured 23° 20′.]

With regard to the mock moons, they were perfectly equidistant from the horizon all the time I observed them, and I regret that I did not notice that Mr. Mott had seen them otherwise. I read his letter rather hurriedly and thought the expression "out of place" referred to their position above the moon, and not to a want of parallelism with the horizon. SM.

Temple Observatory, Rugby, May 17

Mock Moons

I NEVER noticed that mock moons and mock suns are not always at the same altitude as the moon or sun, but I would point out that when objects are high up, it is very difficult to decide on their relative altitudes. If mock moons are at the same altitude as the moon, then of course they are not on a great circle, but on a small one, and in consequence, except when they are low down, a straight line passing through the mock moons will pass above the moon, and when they are high up, at a considerable distance above it. In such a case, if the observer does not look straight at the moon, he may easily suppose that one of the mock moons is higher up than the other. Is your correspondent (vol. xxvii. p. 606) *sure* that they were not at the same altitude on the occasion he refers to? If, instead of facing the moon and looking straight at it, he looked more at the right-hand mock moon, the illusion would be produced of the left-hand one appearing higher up. The same illusion is caused when the horizontal lines of buildings or of a window cut the line passing vertically through the moon obliquely; so that great care is required in making these observations.

I might add that I observed the mock moons and halos on the evening alluded to (April 16) from Sunderland till after 11 p.m., and that I noticed nothing unusual in their positions or size. The mock moons (or suns) are always outside the ordinary halo when their altitude is considerable. On that occasion there was also visible a considerable part of the horizontal halo passing through the mock moons, forming long tails to them away from the moon; also vertical and horizontal rays proceeding from the moon; forming a faint cross with the moon at its centre. The horizontal rays were narrow, and reached at one time to the ordinary halo, but were much fainter than the "tails" of the mock moons. The vertical rays did not reach quite so far, and were broad and indefinite; otherwise I suppose their character (except as to brightness) would be much the same as that of the "sun pillar" described by several of your recent correspondents.

Sunderland, May 12

Helix pomatia

ALTHOUGH this species is decidedly local in this country, yet it is interesting to note that the counties in which it has been recorded are contiguous to one another. Its course of distribution appears to pass through Kent, Sussex, Surrey, Hants, Wilts, Gloucestershire, Berks, Oxon, Bucks, Herts, and Northamptonshire, and this seems to support Mr. Stokoe in his suggestion (NATURE, vol. xxviii. p. 6) that it may be a geologically recent importation from France (to the *northern* portion of which it is confined in that country).

In Murray's "Handbook to Surrey," p. 70, *Helix pomatia* is stated to abound at Tyting Farm near Guildford, "said to have been introduced from Italy" by an Earl of Arundel, and Bevan's "Guide to Surrey," p. 111, mentions the same locality as the "habitat of the edible snail imported from Italy," &c. I visited this spot in September, 1880, in quest of *H. pomatia*, and mentioned my object to a farm labourer, who speedily produced three specimens from under a log of wood, but told me that they were not at all plentiful there, as the soil was *sandy* and not *chalky*, and he said I must look for them on the neighbouring chalk downs, whence his master the farmer procured his for the purpose of adopting the diet, which, when ill, he had been advised to try. Be *H. pomatia* indigenous or not, there is no doubt its presence in England has been assisted by importations, for Mr. Lovell Reeve mentions its being introduced from Italy by an English nobleman in the vicinity of Box Hill and Reigate (cf. also Gray's "Turton," ed. 1840, p. 35).

The *Helix scalaris* referred to in Venables' work on the Isle of Wight is cited in that book as a monstrosity of *H. aspersa*, and Moquin Tandon's figure of the variety *scalaris* is of the usual coloration of that species. The name, however, was originally bestowed by Müller on a variety of *H pomatia* (Lamk. "An sans vert," second edition, vol. viii. p. 32), and is figured as such by Draparnaud, but Venables' reference seems to apply to a scalariform variety of *H. aspersa* observed by Dr. Gray near Ventnor.

Cape Bees

I CAN endorse all that Sir J. H. de Villiers says concerning the sense of smell in the wild bees of the Cape. The aversion they have to sweating horses is well known, as also to the scent of chopped carrots. The following instances of this have come under my own notice:—

A party of young men who had been springbok hunting all the morning, off-saddled their horses during the hottest part of the day, under the shadow of a great krantz (cliff); they had but just tied them to some trees, when the poor animals were attacked in the most vicious manner by an immense swarm of rock bees from the krantz, and so dreadfully were they stung, that, although the thongs that bound them were cut through as quickly as possible to enable the poor things to escape, one beautiful horse was stung to death, and two more of the number were so maddened that they galloped off, and for many days were quite unfit for use.

One of the Hottentot children upon our place, playing in the garden near some hived wild bees, mischievously chewed up a carrot, and spat it into the entrance of the hive; the boy was perfectly naked, and the next few minutes might have been his last, had not the European gardener happened to be near, and hearing his shrieks, hastened to the spot, thrust the child into a newly-dug trench, and quickly covered him with earth; but he had a narrow escape of his life, for he was literally covered with stings.

The precursor of a storm in the Karoo is generally a whirlwind of dust, and our boys used to take advantage of the dislike to storms evinced by bees, to throw up large handfuls of dust into the air, when a swarm was passing overhead, when sometimes the bees would be deceived and settle immediately.

M. CAREY-HOBSON

Late of Graaff Reinet, Cape of Good Hope

The Effect of the Change of Colour in the Flowers of "Pulmonaria officinalis" upon its Fertilisers

YESTERDAY I had an opportunity of convincing myself by direct observation that the change of colour in the flowers of *Pulmonaria officinalis* is of the same significance as in *Ribes aureum* and Lantana, according to Delpino and Fritz Müller (compare NATURE, vol. xvii. p. 79).

In a small locality about twenty yards long and two broad, where many hundred flowers of Pulmonaria were in all stages of development, its principal fertilisers were the females of *Anthophora pilipes*, F.; they visited almost exclusively the red flowers and those just beginning to change towards blue, but only exceptionally blue ones.

The first individual which I watched when it was flying from flower to flower did so without any exception. Another individual newly alighting on the place at first now and then visited one or some few blue flowers, but the longer it continued its predatory flight the more it neglected the blue flowers and selected only the red ones.

A third female of Anthophora which I followed indiscriminately visited (*a*) red flowers of Pulmonaria, (*b*) large blue flowers of Glechoma, both in the following order:—(*a*) 16, (*b*) 1, (*a*) 23, (*b*) 1, (*a*) 21, (*b*) 62, (*a*) 5 flowers; then it left the place without having touched a single blue flower of Pulmonaria.

The fourth and last female of Anthophora I followed neglected completely the flowers of Glechoma; but when it visited the red flowers of Pulmonaria and met for some time only with already emptied ones, it became more and more disturbed and hurried, and then indiscriminately visited blue and red flowers until anew it found honey in a red one. It visited (*a*) red and (*b*) blue flowers of Pulmonaria in the following order:—(*a*) 52, (*b*) 1, (*a*) 18, (*b*) 3, (*a*) 16, (*b*) 1, (*a*) 34, (*b*) 3, (*a*) 7, (*b*) 1, (*a*) 42, (*b*) 1, (*a*) 13; in summa (*a*) 182 red, (*b*) 10 blue flowers.

It is easy to be seen whether a flower of Pulmonaria when visited by Anthophora contains some honey or not; in the first case the proboscis of the bee rests at least 1 to 1½ seconds in the corolla tube, whereas in the other case it is instantly withdrawn. All blue flowers of Pulmonaria which were visited proved thus to be empty of honey, and in all which I examined with a lens in this locality the stigma was supplied with pollen.

We may, I think, safely conclude from these observations that the blue colour of older flowers of Pulmonaria, whilst increasing the conspicuousness of the clusters of flowers, at the same time indicates to such intelligent bees as Anthophora to which flowers they have to restrict their visits as well to their own as to the plant's profit.

HERMANN MÜLLER

The Soaring of Birds

In the discussion about the soaring of birds which has lately been carried on in NATURE, I do not remember to have observed that any one quoted from Mr. Darwin's account of the condor. He says ("A Naturalist's Voyage Round the World," chap. ix. p. 186):—"When the condors are wheeling in a flock round and round any spot their flight is beautiful. Except when rising from the ground, I do not recollect ever having seen one of these birds flap its wings. Near Lima, I watched several for nearly half an hour, without once taking off my eyes: they moved in large curves, sweeping in circles, descending and ascending without giving a single flap. . . . The head and neck were moved frequently, and apparently with force; and the extended wings seemed to form the fulcrum on which the movements of the neck, body, and tail acted. If the bird wished to descend, the wings were for a moment collapsed; and when again expanded with an altered inclination, the momentum gained by the rapid descent seemed to urge the bird upwards with the even and steady movement of a paper kite. In the case of any bird *soaring*, its motion must be sufficiently rapid, so that the action of the inclined surface of its body on the atmosphere may counterbalance its gravity."

Cambridge, May 17 JAMES CURRIE

Intelligence in a Dog

Some time since a friend of mine, Mr. J. W. Schaub, a mechanical engineer at the Edgmore Ironworks of Wilmington, Del., informed me of an exceedingly interesting case of intelligence in a black and tan terrier belonging to him. The old mother dog and her playful family entered his bedroom while he was dressing, and one of the pups snatched his stocking as he was in the act of putting it on, running out of the room with it. The mother at once followed the young offender, took the stocking from him, and returned it to the master. Mr. Schaub said that her conduct gave evidence of displeasure at the action of the pup, and she impressed him with the idea that she felt in some way responsible for the conduct of her young. Being greatly interested in the matter, Mr. Schaub contrived to have the offence committed on many successive mornings, the same performance being repeated each time.

St. Louis, U.S., April 24 FRANCIS E. NIPHER

Mid-height of Sea Waves

Can any of your readers furnish me with the formula, or other means, for finding the difference between the mid-height of a sea-wave and the sea-level? W. PARFITT

A CURIOUS SURVIVAL

The thirteenth Annual Report of the Deputy Master of the Mint, just issued, contains some interesting information showing how persistently an ancient system of computing the value of bullion has survived in this country. The facts are fully set forth in an appendix to the Report by Prof. Chandler Roberts, who has recently and successfully advocated the adoption of the decimal system in the bullion transactions of the Mint. In order to make the matter clear, it may be well to state that the Troy pound, still used in this country for weighing the precious metals, is believed to have been derived from the Roman weight of 5759·2 grains, the 125th part of the large Alexandrian talent; this weight, like the Troy pound, having been divided by the Romans into 12 ounces. The earliest statute of this kingdom in which the Troy weight is named is the 2 Henry V. st. 2, c. 4, but the Troy weight is universally allowed to have been in general use from the time of King Edward I. The most ancient system of weights in this kingdom was the Moneyer's pound or the money pound of the Anglo-Saxons, which was continued in use for some centuries after the Conquest, being then known as the "Tower pound," or sometimes the Goldsmith's pound. It contained 12 ounces of 450 grains each, or 5400 grains, and this weight of silver was a pound sterling. The Tower pound was abolished in 1527 by a statute of Henry VIII., which first established Troy weight as the only legal weight for gold and silver, and from this time to the present our system of coinage has been based on the Troy weight, the Troy pound containing 5760 grains.[1]

The bullion transactions of the Mint have hitherto been based on an Assayer's weight termed the "carat pound," the final division of which corresponds with the number of grains in the Troy pound, and side by side with this system a curious method of expressing the 'standard' or composition of ingots or coins of gold and silver has been retained until the present year. For instance, the ordinary conception of the composition of a sovereign would be that it is an alloy or mixture of the two metals gold and copper in definite proportions, and the most simple way of expressing its contents would be to describe them as consisting of 91·66 per cent. of gold and 8·34 per cent. of copper. An assayer or bullion dealer, on the other hand, using the old system, would simply consider the composition of the coin to be gold of 'standard fineness,' that is to say, containing two carats of alloying metal in the pound; and in dealing with any particular alloy of gold and copper would in no way regard its per-centage composition, but would consider it as being so much "better" or "worse" than the one definite and legal standard, according as it contained more or less of the precious metal. The French 20-franc piece, which contains 90 per cent. of gold, would thus be described as "worse 0 carats $1\frac{5}{8}$ carat grains," and an Austrian ducat, which contains 98·61 per cent. of gold, as "better 1 carat $2\frac{5}{8}$ carat grains." The cumbersome nature of this system is evident; it has the disadvantage of being unintelligible to those who employ the decimal system, and who are therefore in the habit of mentally referring to pure gold as 1000 It is even found wanting in clearness by many who are conversant with the ordinary operations of coinage and bullion transactions generally. For instance, the meaning of "worse 0 $1\frac{5}{8} + 1$" as the assay report of an ingot is at least obscure, while the equivalent statement that the standard fineness of the ingot is 900 at once suggests that 1000 parts of the metal contain 900 parts of gold.

The ancient system of reporting the results of assays possesses however many points of interest, and Prof. Roberts adds a few details respecting it, taken from a work by Snelling,[2] an authority on the computation of the value of bullion, who, writing in 1766, observes that "by the word SILVER we understand not only the metal so-called, pure and unmixed, but also when in a mass with copper; and if but one-half, two-thirds, or any other proportional part of it be silver, yet the whole bears that name. The same is to be understood of GOLD, when by itself, or in a mass with silver and copper together, or with either of them alone."

"This is the reason that inquiries are not made, what quantity of fine gold or fine silver is contained in any mixture, which seems to be the most natural inquiry, but how much standard it holds." Thus it is that "the Assay Master, in reporting the result of an assay, does not give the absolute fineness or the quantity of fine silver or fine gold present, but only the relative quantity or fineness, that is, how much the mixture is more or less than standard. In the case of gold of 20 carats fine (or 20 parts of pure gold in 24 parts of the alloy) the assayer puts down **Wo.** $\overset{\text{car.}}{\text{ij.}}$, and if it is 23 carats $3\frac{1}{2}$ grains fine, he puts down **Br.** $\overset{\text{car.}}{\text{j.}}$ $\overset{\text{gr.}}{\text{iij.}}$ ob." The last sign represents an obolus or half of a carat grain, but in modern times the final division has been 1/60th of a carat grain.

It may be pointed out in defence of this complicated system, that, as Snelling proceeds to remark, "the quan-

[1] "On the Abolition of the Troy Pound," the third Report of the Commissioners appointed to inquire into the condition of the Exchequer Standards. Parliamentary paper [c. 30], 1870.

[2] "Doctrine of Gold and Silver Computations," by Thomas Snelling. (London, 1766.)

tity of "betterness" or "worseness" in an ingot being added to or subtracted from the weight of it, gives the quantity of standard metal contained in it," and that therefore the "betterness" or "worseness" affords a ready means of determining the amount of copper or gold required to standardise the whole. Further, if a number of ingots of varying weights and fineness have to be dealt with, a similar result will be arrived at by taking the algebraical sum of the several products of their weights and "betterness" or "worseness." These advantages, however, apply to individual calculations, and become unimportant when standarding tables adapted to the decimal system are available.[1]

In a letter to Mr. Fremantle, Prof. Roberts advocated the abolition of this old system of carats and grains and the adoption of the decimal system. This has accordingly been carried into effect. Gold of the value of two millions sterling has recently been imported for coinage, and the simplicity and accuracy of the new system has been abundantly demonstrated.

The facts above stated may seem comparatively unimportant in themselves, but the Mint may at any time be called upon to coin (as was the case in 1872) fifteen millions sterling of gold in a single year, and extreme care has to be taken to insure accuracy in the standard fineness of the metal. It is curious that the old system described above should not have given place before now to that which has long been adopted in other countries.

THE POISONOUS LIZARD[2]

THE Gila Lizard of Arizona and Sonora has anterior, deciduous, grooved teeth, which communicate by ducts with large glands within the angle of th ower jaw —an apparatus so strongly resembling the poison-fangs of serpents as to suggest that this lizard has venomous properties. It is said by the natives of Mexico to be very poisonous, but others again have declared that it is perfectly harmless. One specimen sent to Sir John Lubbock killed a frog in a few minutes and a guinea-pig in three minutes.

The conflicting statements are probably due to the fact that the teeth are very small and easily removed. Some specimens of the creature reach the length of three feet. As experiments made by allowing the lizard to bite animals are untrustworthy on account of the uncertainty of getting the poison equally introduced into the tissues at every bite, Doctors Weir Mitchell and Reichert collected the saliva so as to be able to inject it in known quantities. The saliva was obtained by making the animal bite on a saucer-edge. It dropped in small quantities from the lower jaw, and had a faint and not unpleasant aromatic odour. It was distinctly alkaline, in contrast to serpent venoms, which are all alike acid. Four and a half minims of it diluted with half a cubic centimetre of water and injected into the breast of a large pigeon caused the bird to walk unsteadily after three minutes. At the same time the respiration became rapid and short, and at the fifth minute feeble. At the sixth minute the bird fell in convulsions with dilated pupils, and was dead before the end of the seventh minute. There was not the least trace of any local effect of the poison, as there would have been in the case of crotalus venom. The muscles and nerves were perfectly sensitive to stimulation mechanically or by weak induced currents. The heart was arrested in complete diastole, and was full of firm, black clots. The intestines looked congested. In another experiment it was found that the poison gradually lowered the arterial tension and rendered the pulse irregular. Its action on the pulse is not due to any effect upon the pneumogastric nerves, as it is just the same when these nerves are cut. When applied to the heart of a frog it arrests its pulsations in diastole, and the organ afterwards contracts slowly—possibly in rapid *rigor mortis*. The cardiac muscle loses its irritability to stimuli at the time it ceases to beat. The other muscles and nerves respond readily to irritants, but the spinal cord has its power annihilated abruptly and refuses to respond to the most powerful electrical currents.

The authors conclude that "this interesting and virulent heart poison contrasts strongly with the venoms of serpents, since they give rise to local hemorrhages, and cause death chiefly through failure of the respiration and not by the heart, unless given in overwhelming doses. They lower muscle and nerve reactions, especially those of the respiratory apparatus, but do not as a rule cause extreme and abrupt loss of spinal power. Finally, they give rise to a wide range of secondary pathological appearances which are absent from Heloderma poisoning."

This distinction between the action of the poison of Heloderma and serpent venom is correct as far as regards the poison of the rattlesnake and perhaps also the Crotalidæ generally, but the distinction is by no means marked between the poison of Heloderma and the venom of the cobra. This venom was found by Sir Joseph Fayrer and Dr. Lauder Brunton to have but a slight local action as contrasted with that of the rattlesnake or of the daboia, and to produce no local hemorrhage. The effect of cobra poison on birds also is very much the same as that of the Heloderma; and in the experiments given in this preliminary paper, the effect of the Heloderma poison on the heart of the frog is very much like that of cobra poison, the failure of action with subsequent and gradually increasing contraction being almost precisely the same.[1]

In Brunton and Fayrer's experiments on cobra poison, the fall of blood-pressure was less marked, but it still occurred. Paralysis of the spinal cord also is produced by cobra poison, and the experiments in this preliminary paper are too few to enable us to decide whether the paralysing effect is greater from the poison of Heloderma than from cobra venom. We shall look with much interest to the further study of the venom of this curious animal, which the authors intend to make on the arrival of the fresh specimens which they are about to receive.

ON THE CONDENSATION OF VAPOUR FROM THE FUMAROLES OF THE SOLFATARA OF POZZUOLI

THE fumaroles of the Solfatara of Pozzuoli, and especially the larger fumarole known as the *Bocca della Solfatara*, give a striking illustration of the action of smoke in causing the condensation of aqueous vapour in the manner demonstrated by the experiments of Coulier, and more especially by those of Dr. Aitken.

Persons who have visited the Solfatara will remember that one of the feats by which the *ciceroni* of the place try to excite the wonderment of visitors is to light some paper or a few dry branches, and put the flaming body before or inside the mouth of the principal fumarole, augmenting thus very greatly the volumes of cloudy vapour escaping from the fissure. This phenomenon can be observed in all volcanic fumaroles. A flame is not indispensable, the condensation of the vapour being also produced by the mere smouldering of tinder.

Prof. Piria first tried to explain the phenomenon. He thought that small quantities of sulphuretted hydrogen issued from the soil together with the aqueous vapour:

[1] Tables on the system above described were first published in the year 1651, having been prepared by Mr. Reynolds, Assay Master at the Mint in the Tower A second edition was afterwards issued with corrections and additions in 1677.

on mixing with air and coming in contact with a flame, or an incandescent body, the hydrogen sulphide would be oxidised, and resolved in sulphur and water (with the production of small quantities of sulphur dioxide); the sulphur, minutely divided, would remain long suspended in air, and cause the condensation to cloudy consistency of the aqueous vapour. Piria illustrated his explanation by a simple experiment: if in a vessel containing a mixture of sulphuretted hydrogen and air a lighted taper is introduced, a dense mist is rapidly formed; a similar mist is produced when glowing charcoal, or highly heated lava, or pumice, or glass, or red-hot iron is introduced in the gaseous mixture. When there is a large proportion of H_2S, the oxidation is very rapid, and the mixture explodes and burns.

Piria's explanation cannot be applied to the *Bocca della Solfatara*, where the presence of H_2S cannot be detected either by the sense of smell, or by the lead-acetate test-papers. In the "Memorie Geologiche sulla Campania (*Rendiconti della Reale Accademia delle Scienze di Napoli*, 1849, p. 137) Prof. A. Scacchi, after having opposed Piria's opinion, gives the following explanation: "I believe the increase of the vapoury cloud due to the carbonic acid produced in the combustion of the tinder, its affinity for water causing the precipitation of the invisible vapour, and thus producing a mist." According to Prof. Scacchi, in the presence of large quantities of aqueous vapour, and at the temperature of the fumarole, carbonic dioxide would act as hydrochloric acid gas which fumes in ordinary air.

Since 1849 no one (as far as I have gathered) has suggested any new opinion or tried some experiment to explain the phenomenon in question. I thought it would be interesting to test experimentally at the Solfatara the opinion of Prof. Scacchi. I was inclined to believe that, if at the ordinary temperature carbonic dioxide does not condense aqueous vapour from the air, there was very little probability that the condensation would be caused at temperatures as high as those of the vapours issuing from the Bocca of the Solfatara (about 90° Centigrade externally); the action of flames or smouldering bodies in augmenting the vapoury cloud appeared to me as chiefly due to the condensation around the minute particles of soot or dust produced during the combustion.

The following experiments were done during a clear day, when abundant vapours were issuing from the large fumarole:—

1. A Wolff bottle (1 litre capacity), from which a constant current of carbon dioxide was obtained (by pouring dilute hydrochloric acid on marble fragments), was placed on the ground inside the fumarole. The cloud of vapour augmented.

2. By means of a caoutchouc tube the CO_2 from the generator was conducted near the hottest invisible vapour. This vapour became interspersed with cloudlets of condensed vapour, and the cloudy pillar outside the Bocca greatly augmented.

3. A large bottle (of about 15 litres capacity) filled with carbon dioxide was brought inside the cavity, and the CO_2 poured out. The effect was most striking outside by the voluminous, but not immediate, outbursts of cloudy vapour.

4 With bellows of the kind used for sulphuring vines, I blew sulphur dust inside the cavity. This caused the production of great volumes of visible vapour. The same effects were produced every time that minutely divided bodies (wheaten flour, oxide of magnesia, chalky dust, &c.) were blown, or thrown, inside the cavity or near the invisible vapour.

5. The effect was very striking when the action of the carbon dioxide (from the Wolff bottle) was combined with the action of the sulphur dust.

6. A small alcohol flame augmented the cloudiness of the vapour.

7. The smoky flame of burning naphthalene acted much more powerfully than the alcohol flame.

From these experiments, which (with the exception of 3 and 6) were often repeated, the following conclusions may be drawn:—

1. Carbon dioxide helps to condense watery vapour.

2. Minute bodies suspended in air are a powerful cause (the principal cause, as Coulier and Aitken have shown) in the condensation of aqueous vapour.

3. The action of flames, or of incandescent bodies, in augmenting so remarkably the volumes of visible vapour rising from the fumaroles of the Solfatara must be ascribed both to the carbon dioxide and to the minute carbonaceous particles set free during the combustion.

Of these conclusions the first requires to be confirmed by careful laboratory experiments. ITALO GIGLIOLI

STATE OF THE ATMOSPHERE WHICH PRODUCES THE FORMS OF MIRAGE OBSERVED BY VINCE AND BY SCORESBY

In 1881, when I wrote the article *Light* for the *Encyc. Britt.*, I had not been able to meet with any detailed calculations as to the probable state of the atmosphere when multiple images are seen of objects situated near the horizon I had consulted many papers containing what are called "general" explanations of the phenomena, but had found no proof that the requisite conditions could exist in nature:—except perhaps in the case of the ordinary mirage of the desert, where it is obvious that very considerable temperature differences may occur in the air within a few feet of the ground. But this form of mirage is essentially unsteady, for it involves an unstable state of equilibrium of the air. In many of Scoresby's observations, especially that of the solitary inverted image of his father's ship (then thirty miles distant, and of course far below the horizon), the *details* of the image could be clearly seen with a telescope, showing that the air must have been in equilibrium. The problem seemed to be one well fitted for treatment as a simple example of the application of Hamilton's *General Method in Optics*, and as such I discussed it. The details of my investigation were communicated in the end of that year to the Royal Society of Edinburgh, and will, I hope, soon be published. The paper itself is too technical for the general reader, so that I shall here attempt to give a sketch of its contents in a more popular form. But a curious little historical statement must be premised.

It was not until my calculations were finished that I found a chance reference to a great paper by Wollaston (*Phil. Trans.* 1800). I had till then known only of Wollaston's well-known experiment with layers of different liquids in a small vessel. But these, I saw, could not reproduce the proper mirage phenomena, as the rays necessarily enter and emerge from the transition strata by their *ends* and not by their lower *sides*. This experiment is by no means one of the best things in Wollaston's paper, so far at least as the immediate object of the paper is concerned. That so much has been written on the subject of mirage during the present century, with only a casual reference or two to this paper, is most surprising. It may perhaps be accounted for by the fact that Wollaston does not appear to have had sufficient confidence in his own results to refrain from attempting, towards the end of his paper, a totally different (and untenable) hypothesis, based on the effects of aqueous vapour. Be the cause what it may, there can be no doubt that the following words of Gilbert were amply justified when they were written, early in the present century:—"In der That ist Wollaston der Erste und Einzige, der die *Spieglung aufwärts* mit Glück zu erklären unternommen hat." For his methods are, in principle, perfectly correct and suffi-

ciently comprehensive; while some of his experiments imitate closely the state of the air requisite for the production of Vince's phenomena. Had Wollaston only felt the necessary confidence in his own theory, he could hardly have failed to recognise that what he produced by the extreme rates of change of temperature in the small air-space close to a red-hot bar of metal, could be produced by natural rates of change in some ten or twenty miles of the atmosphere:—and he would have deserved the credit of having completely solved the problem.

Six months after my paper was read, another happy chance led me to seek for a voluminous paper by Biot, of which I had seen no mention whatever in any of the books I had previously consulted. The probable reason for the oblivion into which this treatise seems to have fallen is a curious one. It forms a considerable part of the volume for 1809 of the *Mém de l'Institut.* But in the three first great libraries which I consulted, I found this volume to be devoid of plates. In all respects but this, each of the sets of this valuable series appeared to be complete. Without the figures, which amount to no less than sixty-three, it is practically impossible to understand the details of Biot's paper. The paper was, however, issued as a separate volume, "*Récherches sur les Réfractions extraordinaires qui ont lieu près de l'horizon*" (Paris, 1810), which contains the plates, and which I obtained at last from the Cambridge University Library. I have since been able to procure a copy for the Edinburgh University Library. Biot's work is an almost exhaustive one, and I found in it a great number of the results which follow almost intuitively from my methods:—such as the possible occurrence of *four* images, under the conditions usually assumed for the explanation of the ordinary mirage; the effects of (unusual) refraction on the apparent form of the setting sun; &c. But it seems to me that Biot's long-continued observations of the phenomena as produced over extensive surfaces of level sand at Dunkirk have led him to take a somewhat onesided view of the general question. And, in particular, I think that his attempted explanation of Vince's observations (so far as I am able to understand it; for it is very long, and in parts extremely obscure and difficult, besides containing some singular physical errors) is not satisfactory. His general treatment of the whole question is based to a great extent upon the properties of caustics, though he mentions (as the *courbe des minima*) the "locus of vertices" which I had employed in my investigations, and which I think greatly preferable. There can be no doubt, however, that Biot's paper comes at least next in point of importance to that of Wollaston:—though in his opinion Wollaston's work was complete only on the physical side of the problem. "Sous le rapport de la physique son travail ne laisse rien à désirer."

But, if the chief theoretical papers on the subject have thus strangely been allowed to drop out of notice, the case is quite different with several of those which deal with the observed phenomena. Scoresby's *Greenland*, his *Arctic Regions*, and his *Voyage to the Northern Whale Fishery*, are still standard works; and in them, as well as in vols. ix. and xi. of the *Trans. R.S.E.*, he has given numerous careful drawings of these most singular appearances. The explanatory text is also peculiarly full and clear, giving all that a careful observer could have been expected to record. It is otherwise with the descriptions and illustrations in Vince's paper (*Phil. Trans.* 1799). In fact the latter are obviously not meant as *drawings* of what was seen; but as *diagrams* which exhibit merely the general features, such as the relative position and magnitude of the images:—the details being filled in at the option of the engraver. That such was the view taken by Brewster, is obvious from the illustrations in his *Optics* (*Library of Useful Knowledge*), for while one of Scoresby's drawings is there *copied*, one of Vince's is treated in a highly imaginative style by the reproducer.

Scoresby's sketches are composite, as he takes care to tell the reader, so that in the reproduction below (Fig. 1) I have simply selected a few of the more remarkable portions which bear on the questions to be discussed. It is to be

Fig. 1.

remarked that the angular dimensions of these phenomena are always of *telescopic* magnitude:—the utmost elevation of an image rarely exceeding a quarter or a third of a degree.

Because the rays concerned are all so nearly horizontal, and (on the whole) *concave* towards the earth; and because they must also have on the whole considerably greater curvature than the corresponding part of the earth's surface, especially if they happen to have points of contrary flexure; it is clear that, for a preliminary investigation, we may treat the problem as if the earth were a plane. This simplifies matters very considerably, so that definite numerical results are easily obtained; and there is no difficulty in afterwards introducing the (comparatively slight) corrections due to the earth's curvature. But these will not be farther alluded to here.

Of course I began, as almost every other person who has thought of the production of the ordinary mirage of the desert must naturally have begun, by considering the well-known problem of the paths of projectiles discharged from the same gun, with the same speed but at different elevations of the piece. This corresponds, in the optical problem, to the motion of light in a medium the square of whose refractive index is proportional to the distance from a given horizontal plane. Instead, however, of thinking chiefly of the different elevations corresponding to a given range, I sought for a simple criterion which should enable me to decide (in the optical application) whether the image formed would, in any particular case, be a direct or an inverted one. And this, I saw at once, could be obtained, along with the number and positions of the images, by a study of the form of the locus on which lie the *vertices* of all the rays issuing from a given point. Thus, in the ballistic problem, the locus of the vertices of all the paths from a given point, with different elevations but in the same vertical plane, is an ellipse.

Its minor axis is vertical, the lower end being at the gun; and the major axis (which is twice as long) is in the plane of projection. Now, while the inclination of the piece to the horizon is less than 45°, the vertex of the path is in the *lower* half of this ellipse, where the tangent leans forward from the gun; and in this case a small increase of elevation *lengthens* the range, so that the two paths do not intersect again above the horizon. In the optical problem this corresponds to an *erect* image. But, when the elevation of the piece is greater than 45°, the vertex of the path lies in the *upper* half of the ellipse, where the tangent leans back over the gun; and a small increase of elevation *shortens* the range. Two contiguous paths, therefore, intersect one another again above the horizon. And, in the optical problem, this corresponds to an *inverted* image. In symbols, if the eye be taken as origin and the axis of x horizontal, there will be a direct image for a ray at whose vertex dy/dx and x (in the curve of vertices) have the *same* sign, an inverted image when the signs are different.

Hence, whatever be the law of refractive index of the air, provided only it be the same at the same distance from the earth's surface, (*i.e.* the surfaces of equal density parallel planes, and therefore the rays each symmetrical about a vertical axis) all we have to do, in order to find the various possible images of an object at the same level as the eye, is to *draw the curve of vertices for all rays passing through the eye, in the vertical plane containing the eye and the object, and find its intersections with the vertical line midway between the eye and the object.* As soon as this simple idea occurred to me, I saw that it was the very kernel of the matter, and that all the rest would be mere detail of calculation from particular hypotheses. Each of the intersections in question is the vertex of a ray by which the object can be seen, and the corresponding image will be erect or inverted, according as the curve of vertices leans from or towards the eye at the intersection. Thus, in Fig. 2, let E be the eye, and

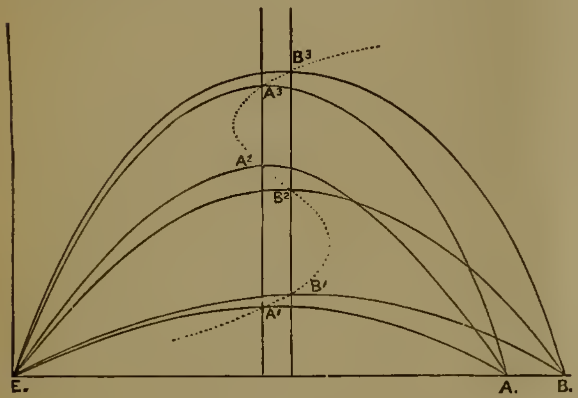

Fig. 2.

the dotted line the curve of vertices for all rays in the plane of the paper, and passing through E. Let A be an object at the level of the eye, $A^1 A^2 A^3$ the vertical line midway between E and A. Then A^1, A^2, A^3 are the vertices of the various rays by which A can be seen. If we make the same construction for a point B, near to A, we find that whereas the contiguous rays through A^1, B^1 and through A^3, B^3 do not intersect, those through A^2, B^2 do intersect. At A^1 and A^3 the curve of vertices leans *from* the eye, and we have erect images; at A^2 it leans back *towards* the eye, and we have an inverted image. And thus, if this curve be continuous, the images will be alternately erect and inverted. The sketch above is essentially the same as one given by Vince, only that he does not employ the curve of vertices. If the object and eye be not at the same level, the construction is not *quite* so simple. We must now draw a curve of vertices for rays passing through the eye, and another for rays passing through the object. Their intersections give all the possible vertices. (This construction of course gives the same result as the former, when object and eye are at the same level.) But the images are now by no means necessarily alternately erect and inverted, even though the curve of vertices be continuous. However, I merely note this extension of the rule, as we shall not require it in what follows.

I then investigated the form of the curve of vertices in a medium in which the square of the refractive index increases by a quantity proportional to the square of the distance from a plane in which it is a minimum, and found that (under special circumstances, not however possible in air) three images could be produced in such a medium. But the study of this case (which I could not easily explain here without the aid of mathematics) led me on as follows.

As the curvature of a ray is given by the ratio of the rate of change of index per unit of length perpendicular to the ray, to the index itself (a result which I find was at least virtually enunciated by Wollaston); and as all the rays producing the phenomena in question are very nearly horizontal:—*i.e.* perpendicular to the direction in which the refractive index changes most rapidly:—their curvatures are all practically the same at the same level. Hence if the rate of diminution of the refractive index, per foot of ascent, were nearly constant, through the part of the atmosphere in which the rays travel, the rays we need consider would all be approximately arcs of equal circles; and the curve of vertices would (so far as these rays are concerned) lean wholly *from* the eye; being, in fact, the inferior part of another equal circle which has its lowest point at the eye. Hence but one image, an erect one, would be formed; but it would be seen elevated above the true direction of the object. This is practically the ordinary horizontal refraction, so far as *terrestrial* objects on the horizon are concerned. The paths of the various rays would be of the form in Fig. 3 (the drawing

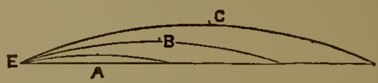

Fig. 3.

is, of course, immensely exaggerated) and the locus of vertices, A B C, obviously leans *from* the eye. But now suppose that, below a stratum of this kind, there were one of constant density, in which of course the rays would be straight lines. Then our sketch takes the form Fig. 4 (again exaggerated); each of the portions of the ray in

Fig. 4.

the upper medium being congruent to the corresponding one in the former figure (when the two figures are drawn to the same scale), but *pushed farther to the right as its extremities are less inclined to the horizon.* In its new form the curve of vertices A B C leans back *towards* the eye, and we have an inverted image. The lower medium need not be uniform as, for simplicity, we assumed above. All that is required is that the rate of diminution of density upwards shall be less in it than in the upper medium.

Those who have followed me so far will at once see that, as a more rapid decrease of density, commencing at a certain elevation, makes the curve of vertices lean back, so a less rapid decrease (tending to a "stationary state") at a still higher elevation will make the curve of vertices again lean forward from the eye. I need not enlarge upon this.

Thus to repeat:—the conditions requisite for the production of Vince's phenomenon, at least in the way conjectured by him, are, a stratum in which the refractive index diminishes upwards to a nearly stationary state, and below it a stratum in which the upward diminution is either less or vanishes altogether. The former condition secures the upper erect image, the latter the inverted image and the lower direct image.

In my paper read to the *Royal Society of Edinburgh* I have given the mathematical details following from the above statement; and have made full calculations for the effect of a transition stratum, such as must occur between two uniform strata of air of which the upper has the higher temperature. From Scoresby's remarks it appears almost certain that something like this was the state of affairs when the majority (at least) of his observations were made. When two masses of the same fluid, at different temperatures, rest in contact; or when two fluids of different refractive index, as brine and pure

water, diffuse into one another; the intervening layer must have a practically "stationary" refractive index at each of its bounding surfaces, and a stratum of greatest rate of change of index about midway between them. The exact law of change in the stratum is a matter of comparatively little consequence. I have assumed (after several trials) a simple harmonic law for the change of the square of the refractive index within the stratum. This satisfies all the above conditions, and thus cannot in any case be very far from the truth. But its special merit, and for my purpose this was invaluable, is that it leads to results which involve expressions easily calculated numerically by means of Legendre's Tables of Elliptic Integrals. This numerical work can be done once for all, and then we can introduce at leisure the most probable hypotheses as to the thickness of the transition stratum, the height of its lower surface above the ground, and the whole change of temperature in passing through it. I need not now give the details for more than one case, and I shall therefore select that of a transition stratum 50 feet thick, and commencing 50 feet above the ground. From the physical properties of air, and the observed fact that the utmost angular elevation of the observed images is not much more than a quarter of a degree, we find that the upper uniform layer of air must under the conditions assigned be about 7° C. warmer than the lower. Hence by the assumed law in the stratum, the maximum rise of temperature per foot of ascent (about the middle of the transition stratum) must be about 0°·2 C. per foot. Such changes have actually been observed by Glaisher in his balloon ascents, so that thus far the hypothesis is justified. But we have an independent means of testing it. The form of the curve of vertices is now somewhat like the full lines in the following cut, Fig. 5:—

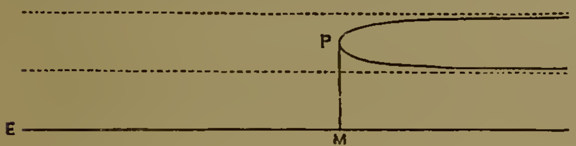

Fig. 5.

where E is the eye, and the dotted lines represent the boundaries of the transition stratum. It is clear that, if P M be the vertical tangent, there can be but one image of an object unless its distance from E is at least twice E M. This will therefore be called the "*Critical distance.*" If the distance be greater than this there are three images:—one erect, seen directly through the lower uniform stratum—then an inverted one, due to the diminution of refractive index above the lower boundary of the transition stratum—and finally an erect image, due to the approximation to a stationary state towards the upper boundary of that stratum. Now calculation from our assumed data gives E M about six miles, so that the nearest objects affected should be about twelve miles off. Scoresby says that the usual distance was from ten to fifteen miles. Thus the hypothesis passes, with credit, this independent and severe test. A slight reduction of the assumed thickness of the transition-stratum, or of its height above the ground, would make the agreement exact.

All the phenomena described in Vince's paper of 1799, as well as a great many of those figured in Scoresby's works, can easily be explained by the above assumptions. Scoresby's remarkable observation of a single inverted image of his father's ship (when thirty miles off, and of course far below the horizon) requires merely a more rapid diminution of density at a definite height above the sea. His figure is the second in Fig. 1 above. But Scoresby figures, as above shown, several cases in which two or more inverted images, without corresponding erect ones, were seen above the ordinary direct image. The natural explanation is, of course, a series of horizontal layers of upward diminishing density and without a "stationary state" towards their upper bounding planes. I find that, by roughly stirring (for a very short time) a trough in which weak brine below is diffusing into pure water above, we can reproduce this phenomenon with great ease. In fact, when temporary equilibrium sets in, the fluids are arranged in a number of successive parallel strata with somewhat abrupt changes of density.

But the mathematical investigation, already spoken of, shows that it is quite possible that there may be layers tending to a stationary state without any corresponding *visible* images.

This depends on the fact that, while the inverted image (due to the lower part of a stratum) is *always* taller than the object seen directly (though not much taller unless the object is about the critical distance); the numerical calculation shows that the erect image is in general extremely small, and can come into notice only when the object is not far beyond the critical distance. Thus there may have been, in *all* of Scoresby's observations (though he has only occasionally noticed and depicted them) an erect image above each inverted one, but so much reduced in vertical height as to have been invisible in his telescope, or at least to have formed a mere horizontal line so narrow that it did not attract his attention. The greatly superior number of inverted images, compared with that of the direct ones, figured by Scoresby may thus be looked upon as another independent confirmation of the approximate correctness of the hypothetical arrangement we have been considering.

To obtain an experimental repetition of the phenomena in the manner indicated by the above hypothesis, a tank, with parallel glass ends, and about 4 feet long, was half-filled with weak brine (carefully filtered). Pure water was then cautiously introduced above it, till the tank was nearly filled. After a few hours the whole had settled down into a state of slow and steady diffusion, and Vince's phenomenon was beautifully shown. The object was a metal plate with a small hole in it, and a lamp with a porcelain globe was placed behind it. The hole was triangular, with one side horizontal (to allow of distinction between direct and inverted images), and was placed near one end of the tank, a little below the surface-level of the unaltered brine, the eye being in a corresponding position at the other end. A little vertical adjustment of object and eye was required from time to time as the diffusion progressed. The theoretical results that the upper erect image is usually much less than the object, and that it is seen by slowly convergent rays, while the inverted image is larger than the object and is seen by diverging rays, were easily verified.

To contrast Wollaston's best-known experiment with this, a narrow tank with parallel sides was half-filled with very strong brine, and then cautiously filled up with pure water. (The strong brine was employed to make up, as far as possible, for the shortened path of the rays in the transition stratum.) Phenomena somewhat resembling the former were now seen, when object and eye were nearly at the same distance apart as before, and the tank about half-way between them. But in this case the disparity of size between the images was not so marked—the upper erect image was always seen by diverging rays, the inverted image by rays diverging or converging according as the eye was withdrawn from, or made to approach, the tank. In this case, the curvature of each of the rays in the vessel is practically constant, but is greatest for the rays which pass most nearly through the stratum of most rapid change of refractive index. Hence, when a parallel beam of light fell horizontally on the tank and was received on a sufficiently distant screen, the lower boundary of the illuminated space was blue—and the progress of the diffusion could be watched with great precision by the gradual displacement of this blue band

I propose to employ this arrangement for the measurement of the rate of diffusion, but for particulars I must refer to my forthcoming paper.

Wollaston's experiment with the red-hot poker was probably, his experiment with the long red-hot bar of iron almost certainly, similar to that above described with the long tank and the weak brine; and *not* to that with the short tank, though the latter is usually cited as Wollaston's contribution to the explanation of the Vince phenomenon. We have seen how essentially different they are, and that the latter does not correspond to the conditions presented in nature. P. G. TAIT

NOTES

THE Council of the Scottish Meteorological Society are soliciting subscriptions, however small, for the proposed Ben Nevis Observatory. It is essential to the success of this important national undertaking that the buildings should be erected during the present summer, and several thousand pounds are required before operations can be commenced. A considerable sum has already been received in liberal subscriptions from a few individuals, but not nearly enough for the purpose. We trust that many of our readers will send what they can to the Scottish Meteorological Society, Edinburgh.

DR. WILD, president of the International Circumpolar observation parties, announces that in conformity with the request of several Governments, the observations now going on round the Pole will not be prolonged beyond the time originally fixed, viz. September, and that all the parties, if not prevented by ice, will be back within that month.

A LETTER read at the Paris Geographical Society states that P. Vidal, French missionary to Samoa, has discovered the remains of La Perouse and his unfortunate companions.

THE Rev. S. J. Perry, S.J., has lately been elected a Corresponding Member of the Accademia dei Lincei.

DR. HENRY SCHLIEMANN has been elected an Honorary Fellow of Queen's College, Oxford.

LAST week we announced that a baronetcy had deservedly been conferred on Dr. William Chambers, and this week we regret to announce the death of the veteran publisher in his eighty-fourth year. As the head of the firm of Messrs. W. and R. Chambers, he has through a long life done splendid service in the spread of education, and of a knowledge of science. In his "Information for the People," his "Tracts," his text-books of science, among the first of their kind, and by various other means, he did good pioneer work in scientific literature and education.

IN reference to our note last week (p. 63), a correspondent writes that the American table at Naples is being used by its first occupant, Dr. E. B. Wilson, of the Johns Hopkins University, Baltimore. Dr. Wilson has been working during a part of the year at Cambridge on early mammalian embryology, and at Naples his work will probably be either on certain points in the development of some of the Cœlenterata or upon the embryology of the Dicegemidæ as available material permits. Williams College, Mass., which holds the American table, receives a brief course of lectures from each worker whom it appoints to the privileges of the Naples Station.

ON the evening of Friday last week several tornadoes swept over the states of Minnesota, Wisconsin, Illinois, and Missouri, which were exceptionally destructive to life and property even for that tornado-troubled region. It is reported that 83 persons have been killed and 340 injured, many of them fatally, and a very large number of houses reduced to ruins. Of these tornadoes the most terrible in its destructiveness would appear to have been the one which passed over Racine in the south-east of Wisconsin, killing 25 and injuring 100 persons, and wrecking 150 buildings. The path of the tornado was about 400 yards wide and half a mile long, and all buildings, particularly those in the central line of its path, collapsed into mere masses of ruins. Waggons and other movable articles were blown into Lake Michigan, over which the tornado passed on leaving the town, the whirling columns of clouds and the violent commotions of the lake presenting a grand and impressive spectacle. The recently published "Professional Papers of the Signal Service, No. VII." show that the region over which these tornadoes passed is comprehended within that portion of the United States where tornadoes are of most frequent occurrence.

MR. BRUNLEES, the President of the Institution of Civil Engineers, has sent out invitations for a *conversazione* at the South Kensington Museum on Wednesday, the 30th inst.

ON Saturday last, May 19, the Essex Field Club held its first meeting of the session. The party, nearly ninety in number, alighted at Theydon Bois Station on the Ongar branch of the Great Eastern Railway, and proceeded through Epping Forest to Ambresbury Banks, where they were met by Sir T. Fowell Buxton. The party was then conducted through the splendid park belonging to the Copt Hall Estate, and finally assembled at Warlies, Waltham Abbey, the seat of Sir Fowell Buxton, who had kindly invited the Club for the occasion. In the course of the evening a paper on "English Plant Names" was read by Mr. J. Britten, F.L.S.

THE Paris Aëronautical Exhibition will be opened at the Trocadéro on June 5 and close on the 18th. MM. Janssen, Berthelot, Paul Bert, and Hervi Mangon are among the members of the committee, as well as a number of senators and deputies. The festival will take place at Annonay on July 29, and statues of the two brothers Montgolfier will be erected on the public place of the city. A competition has been opened in Paris, and the works of competitors are on view at the Cercle de la Librairie. The jurymen, mostly members of the Academy of Beaux Arts, will give their award on Saturday next. The height of the monument and pedestal will be 7 metres. The prize is 3000 francs for the plaster model to be exhibited at Annonay on July 29, and 40,000 francs for the bronze. The marble for the pedestal will be given by Government. A public banquet will be given in Paris, M. Gaston Tissandier being in the chair.

ON April 29, at 10.30 p.m., a brilliant meteor was observed in Joudalen in Norway. It appeared in the east, and went in a southerly direction, where it passed out of sight. Its size to the eye was about the same as the moon's, while its shape appeared to be conic. The colour of its track was deep red, and it shone so brilliantly that the smallest objects could be seen on the ground. It lasted several seconds, and disappeared behind some mountains.

ON the 13th, at 8 o'clock in the evening, a large meteor was observed at Epinal, travelling from south-east to north-west; it had a disk which has been estimated at a decimeter. The tail was of a pinky colour; a noise from explosion was heard. It was also observed at Mulhausen.

THE Reports on the Public Gardens and Plantations in Jamaica are becoming yearly of more importance. That for the year ending September 30 last is now before us. Mr. Morris opens his report by bearing testimony to the liberality of the Steamship and Railway Companies in conveying plants free of charge to the different ports and railway stations. "By these means," it is stated, "districts, formerly beyond the reach of the Public Gardens, have been able to obtain plants as conveniently and as

cheaply as if they were in the neighbourhood of Kingston." It is stated that a drought, caused chiefly by the failure of the May rains coming after a succession of dry months with parching winds, had a prejudicial effect on all agricultural operations. Mr. Morris says: "It is a subject of common remark amongst old planters that the 'seasons,' or the periodical rains which have hitherto fallen with great regularity and copiousness during the months of May and October of each year, are becoming more and more uncertain and irregular, and the effects of these conditions are clearly shown in the precariousness of the agricultural products affected by them. These remarks apply chiefly to the southern slopes of the Blue Mountains, and to such other districts stretching south and west where coffee and provisions are being chiefly raised." Under the head of "Cinchona Plantation," the cultivation of which plants has become an object of special attention in Jamaica, Mr. Morris reports very fully. He says: "In order to test the commercial value of Jamaica grown bark, no better plan could be followed than to send it in lots to the open market and place it in competition with barks from other countries. That it has so satisfactorily stood this test and brought in a large return on the outlay, and, moreover, that the results of the sales have induced cinchona planting to be undertaken in the island by private enterprise with energy and success, are matters for which the Government no less than the general public are to be congratulated." "During the past year chief attention has been given to the successful introduction of *Cinchona Ledgeriana* and its establishment as a cultivated plant in Jamaica. In addition to the plants established on the Government plantations, several thousands have been distributed amongst private planters, and each lot of these will doubtless form a nucleus from whence seeds and cuttings may hereafter be obtained, and thus prove most valuable acquisitions to private plantations." A few plants of the now well known cuprea bark, *Remijia pedunculata*, have been raised from seed received from Bogota, and are being tried in order to test the value of the bark under cultivation. An attempt is about to be made to manufacture cinchona febrifuge in the island in a similar way to what is being now done so successfully in the East Indies. By this means a valuable and cheap preparation will be available for use among the poorer classes. Besides the cinchonas the cultivation of jalap and various other economic plants has received attention during the year, so that we have evidence that a good deal of really useful work is being carried on by Mr. Morris in Jamaica.

A WRITER in the *North China Herald* on the history of gunpowder in China asserts that this explosive was known in the seventh century of our era. The alchemists of the Han dynasty, and subsequently in the fourth and following centuries, worked with saltpetre and sulphur, as well as cinnabar, red oxide of lead, and other common compounds. But in the seventh century we find gunpowder used to make a crackling sound and to afford an agreeable sight to the court of Sui Yang-ti, the emperor of that time. The earliest exhibitions of fireworks mentioned in Chinese history belong to that date. The substances used in the composition of gunpowder are all native to China, and the writer appears to prove conclusively that the Arabs derived the art of firework making, as well as gunpowder, from the Chinese. The discovery once made, the Chinese alchemists, owing to the badness of their hypotheses and the futility of their aims, were slow at improvement. But the doctors of the Arab colonies in China carried to Bagdad the germs of the Chinese discoveries, and there they were elaborated into new forms. In short, in many arts and sciences the Arabs learnt from China, and, assisted by Nestorians, Jews, and Greeks, improved on what they learned. In course of years, cannon, matchlocks, and shells for use in sieges were brought to China from Mohammedan countries. There are faint traces in the eleventh century of rude firearms: in the twelfth and thirteenth centuries the records of their use in the Chinese wars become frequent and distinct. The Golden Tartars, in their wars with South China in the twelfth century, used cannon which they called "heaven-shaking thunder." In an iron tube was placed powder which was "set fire to, and would burn down half a square *li* of houses and pierce a coat of mail made of iron rings." It is expressly stated that Genghis Khan, the Mongol conqueror, used cannon in his wars. Kublai Khan also used these weapons at a siege celebrated in Chinese history—that of Siang-yang. Hearing, it is said, the sound of the explosion, which shook the sky, and seeing that the balls entered seven feet into the earth, the Chinese defenders of the city capitulated. It is clear that China owed its knowledge of artillery to the Mohammedans. In the fourteenth century commenced the European intercourse with China, which then abandoned the Arabs, and took the Portuguese as teachers in the construction of weapons of warfare.

NEWS from Iceland states that from the 12th to the 21st of March there were violent volcanic water eruptions.

A REUTER'S telegram from Hong Kong *viâ* San Francisco announces the completion of the telegraph line between Canton and that colony. This is the second great line in China, and appears to have been constructed wholly by native merchants in Canton, who found the want of early communication with western markets in their commercial transactions. Vigorous preparations are also being made for the most formidable undertaking of this nature that has yet been attempted in China, viz. a line connecting Peking with Canton. According to the latest information an expeditionary party has arrived at Shanghai to conduct the necessary surveys. It will proceed first to Soochow, and there, under the escort of 200 troops, will commence its work, proceeding southward.

A NUMBER of students at the Ecole des Mines of France will during the summer make an excursion to the Arctic regions. A steamer, in charge of a Norwegian Arctic hunter, will bring the party to Throndhjem and Hammerfest, and thence to Spitzbergen, which will be examined during a fortnight's stay. The Naturalistic Museum of Paris sends two *savants* with the party.

THE additions to the Zoological Society's Gardens during the past week include two Green Monkeys (*Cercopithecus callitrichus* ♂ ♀) from West Africa, presented by Mr. Thos. H. Dixon; a Long-eared Owl (*Asio otus*), British, presented by the Rev. H. D. Grantham; a Smooth Snake (*Coronella lævis*), European, presented by Mr. W. H. B. Pain; seven Black and Yellow Cyclodus (*Cyclodus nigro-luteus*) from Tasmania, presented by Baron Ferdinand von Mueller, C.M.Z.S.; a Proteus (*Proteus anguinus*), European, presented by Miss Maud Howard; a Sea Crayfish (*Palinurus vulgaris*), British Seas, presented by Messrs. Milestone and Staniforth; three Green-winged Doves (*Chalcophaps indica*) from India, a Herring Gull (*Larus argentatus*), British, deposited; a King Vulture (*Gypagus papa*) from Tropical America, purchased; a Cabot's Tragopan (*Ceriornis caboti* ♀) from North-West China, received on approval.

OUR ASTRONOMICAL COLUMN

THE COMET OF 1707.—The elements of this comet's orbit, as calculated by Lacaille and Struyck, bear a certain degree of resemblance to those of the comet discovered by De Vico at Rome on February 20, 1846 (1846 IV. of our catalogues), to which Van Deinse's definitive calculation assigns a period of revolution of 73 years. The interval between the perihelion passages in 1707 and 1846 would give two periods of 69·1 years; there is consequently a sufficient reason for examining how far the elements of the comet of 1707 represent the observations. It appears to have been discovered by Manfredi at Bologna on November 25, and the place given in the *Mémoires* of the Paris

Academy for that date was in R.A. 308° 25′, Decl. – 24° 17′. Pingré in his *Cométographie* mentions that according to Struyck this position is erroneous, and that ten minutes should be added to the declination and five to the right ascension as printed in the *Mémoires*, adding that if Lacaille has used the Bologna observation his orbit would be less accurate than that of Struyck. The Bologna observers Manfredi and Stancari found the comet on November 25, in the same field of view of an 8 foot telescope, with two stars, the distance between which they estimated at 9′. At 7h. 14m. 47s. apparent time the centre of the comet was in the right line joining these stars, and its distance from the northernmost star was one-third of the distance between them. It is easy to see from the rough position given, that the stars in question are Piazzi XX., 296 and 298, and carrying back his places, we have for the position of the comet referred to the mean equinox of 1708·0, R.A. 307° 49′·3, Decl. – 23° 44′·1. The equation of time was 12m. 37s. subtractive from apparent time, and hence the Greenwich mean time of observation was November 25·26163. The place calculated from Lacaille's orbit, first published in his "Leçons d'Astronomie," differs + 7′·2 in R.A. and + 5′·6 in Decl., so that it is evident he did not use the position as erroneously deduced in the *Mémoires*. The agreement of his elements with the Paris observation on December 17 is fairly good; there is a much larger deviation from the approximate places determined at Bologna, on January 13 and 17; but these observations of Manfredi and Stancari are probably affected with very material errors, as such is certainly the case with the deduced position for the night of discovery. So far as can be judged from this partial comparison of Lacaille's elements with observation, the hypothesis of identity of the comet of 1707 with that of 1846 is not supported, but the observations of the former may deserve further discussion.

THE TRANSIT OF VENUS.—Prof. C. A. Young has published his observations of all four contacts in the late transit of Venus, made at the Halsted Observatory, Princeton, N.J., with the 23-inch equatorial, and a power of 160. At the two internal contacts the aperture was diminished to 5⅗ inches, "in order to make the observations comparable as far as possible with those of the various government expeditions," but at the external contacts the full aperture was employed; a polarising helioscope was attached. We have compared the times given by Prof. Young with those calculated from the reduction-equations published in this column, in the formation of which it was the main object to get geometrical contacts. It has been previously mentioned that there was a close agreement between prediction and observation in the case of the results obtained at Harvard College, and the following are the small differences (calc.–obs.) for Prof. Young's:—

I. – 16s. ... II. + 3s. ... III. – 15s. ... IV. – 4s.

THE BRITISH ASSOCIATION CATALOGUE OF STARS.—We lately remarked, not without some surprise, that a copy of this work was priced in a continental list of second-hand books at the high figure of 12*l*. 10*s*., or about three times the cost at its publication in 1845. Such a fact naturally induces the query, Is there occasion for a new general catalogue of the principal fixed stars, or, say, of stars within the limit of naked-eye vision? It is a question upon which there will probably be a wide difference of opinion, and it is one that it would be of interest to discuss.

GEOGRAPHICAL NOTES

THE last number of the *Verhandlungen der Gesellschaft für Erdkunde* of Berlin contains a paper by Prof. Brauns, late of Japan, on the Island of Yezo. The writer agrees with Mr. Keane and other ethnologists that the Ainos are a totally different race from the Japanese. The number of these people in Yezo and the Kuriles is given by the Japanese Government as 18,000, but many authors place the number as high as 50,000. In Saghalin there are 10,000 to 12,000, and if those in the southern part of Kamschatka who are living under Russian rule are included, the total number of the race would probably be from 60,000 to 70,000. In the same issue the indefatigable explorer of the Philippines, Herr Jagor, describes briefly a recent journey through Luzon. An interesting communication also is a list of the papers published by the Geographical Society of Tokio in its volume for 1880. This Society is composed, we believe, almost wholly of natives, and its papers are printed in Japanese. There appear to have been in all thirty-eight communications of one kind or another; the writers or translators (for some of the papers are apparently translations from others in European languages) are in all cases Japanese. Among the papers are several on the history and geography of Okinawa, as the Japanese call the Loochoo group; the climate of Peking; Japanese intercourse with foreign countries in the middle ages; a journey to Vladivostock; the history of geography in Japan; history and geography of Persia by a Japanese who had travelled through the country; description of Australia; description of a voyage in the Persian Gulf; of a journey on the Khirgiz steppes; ancient Japanese geographical names; description of Saghalin; on the absence of precious stones in Japan, &c., &c. Some of these papers would hardly meet with a favourable reception from the Council of the Royal Geographical Society; but in Japan they are listened to and read afterwards in their printed form by hundreds of people who have never left their own country, and who possess but a very small geographical literature. When this is remembered, the list will appear not only a creditable one to the travellers, but also a most useful one for the spread of geographical knowledge in Japan, which after all is the purpose of the Society.

THE annual report of Mr. Tremlett, the British Consul at Saigon, contains some interesting geographical information about the northern and less known districts of the Indo-Chinese peninsula. The governor of Cochin China sent out an expedition to explore the country between the Meikong and Annam at about 14° latitude. The party left Peamchileng, on the Meikong, proceeding eastward. After passing the river valley the country became hilly and wooded, intersected with numerous watercourses. No difficulty was experienced until the arrival of the travellers near the Cambodian frontiers. As they proceeded the hostility of the people became yet more pronounced, and finally their passage towards Annam was closed altogether. They were finally compelled to retreat, losing all their baggage on the way, and after three months' absence they reached a friendly post. The Mois inhabit the wilds between Cambodia, Siam, Burmah, and China. Commerce, properly speaking, does not exist among them, and traffic is carried on by exchanges. The various roads and river are stopped up by the people themselves to prevent the passage of pillagers and enemies; as a result the people are very backward. Money is almost unknown or unappreciated among them. A native who will not work for a dollar a day will do so for a bell costing a few cents. The articles most valued by the Mois are buffaloes, red and white cottonades, glass ware, brass wire, utensils, salt, and salt fish.

FROM the same report we learn that an exploration of the upper waters of the Saigon river by Lieut. Gauthier shows that previous charts are incorrect; the names given in them being imaginary. There appears to have existed in this region in former times one or more states in an advanced stage of civilisation, as may be seen by ruins still remaining, probably offshoots of the famous Angker Wat. The present race of Mois claim no descent from their predecessors on the soil, and indeed it would be difficult to find a lower state than theirs. It is difficult to communicate with them, as the language is not easily picked up by the Annamites. They appear to be in a state of independence, paying no tribute to any of their neighbours, although the King of Cambodia is their nominal suzerain. The report concludes by saying that the French Government will have to send a much more serious expedition if anything is to be learned about these regions; two or three men can learn nothing.

THE great attention which France has given for many years past to the Indo-Chinese peninsula is shown by a return printed in the *Proceedings of the Société Académique Indo-Chinoise* of all the scientific expeditions despatched by the French Government to this region. These embrace archæological, ethnological, geographical, and other scientific objects, and up to 1881 they were seventy seven in number. They commence as far back as 1680, when the Jesuit Pallu visited the courts of Tonkin and Annam. Seventeen of these took place before the military occupation of any part of Cochin China by the French; thirty-three were sent by the Ministry of Public Instruction, chiefly for archæological purposes, while the remaining twenty-seven were sent by the Ministry of Marine and the Colonies, and were devoted principally to exploration. To understand the mass of scientific work done by the French in Indo-China, it must be remembered that these seventy-seven expeditions do not include the innumerable journeys and researches of the missionaries,

which commence as far back as the end of the fifteenth century, the various expeditions sent out by private enterprise, those despatched for military, naval, or diplomatic purposes, or, finally, the various hydrographic or geodetic surveys undertaken by the French authorities in Cochin China.

THE teachers at the school for the sons of Japanese nobles in Tokio appear to have hit upon a notable method of teaching physical geography. In the court behind the school building is a physical map of the country, between three and four hundred feet long. It is made of turf and rock, and is bordered with pebbles, which look at a little distance much like water. Every inlet, river, and mountain is reproduced in this model with a fidelity to detail which is wonderful. Latitude and longitude are indicated by telegraph wires, and tablets show the position of the cities. Ingenious devices are employed in illustrating botanical studies also. For example, the pine is illustrated by a picture showing the cone, leaf, and dissected flower, set in a frame which shows the bark and longitudinal and transverse sections of the wood.

IN No. 103 of the *Zeitschaft* of the Berlin Geographical Society will be found a fine series of new large scale maps by H. Kiepert on the region containing the ruins of Babylon, embodying the results of new surveys and explorations. In the same number Herr Karl Schneider has a long paper on the valley formations of the Eifel.

PROF. FRIES has written an interesting paper proposing that part of Greenland should be colonised by Lapps. He maintains that the country would be a paradise to the mountain Lapps, that it is no more inhospitable than their own country, that there would be no restrictions to their wanderings, and that in the interior in summer and on the coast in winter they would find abundant forage for their herds. Prof. Fries is of Nordenskjöld's opinion, that in the interior abundant reindeer pasture will be found. Moreover, as a Lapp can always follow where a reindeer leads, this would be an excellent plan of discovering the true nature of the interior; it seems certainly worth trying.

TWO gentlemen from Münster (Westphalia)—Dr. Bachmann and Dr. Friedrich Wilms—are about to start on a scientific tour to Southern Africa, the Transvaal to begin with, in order to make zoological and botanical researches. Their journey will extend over several years, and the travellers will endeavour to establish direct commercial relations between the South African colonies and Germany.

ELECTRICAL UNITS OF MEASUREMENT[1]

THE lecturer began by observing that no real advance could be made in any branch of physical science until practical methods for a numerical reckoning of phenomena were established. The "scale of hardness" for stones and metals used by mineralogists and engineers was alluded to as a mere test in order of merit in respect to a little understood quality, regarding which no scientific principle constituting a foundation for definite measurement had been discovered. Indeed it must be confessed that the science of strength of materials, so all important in engineering, is but little advanced, and the part of it relating to the quality known as hardness least of all.

In the last century Cavendish and Coulomb made the first advances towards a system of measurement in electrical science, and rapid progress towards a complete foundation of the system was effected by Ampère, Poisson, Green, Gauss, and others. As late as ten years ago, however, regular and systematic measurement in electrical science was almost unknown in the chief physical laboratories of the world; although as early as 1858 a practical beginning of systematic electric measurement had been introduced in the testing of submarine telegraph cables.

A few years have sufficed to change all this, and at this time electric measurements are of daily occurrence, not in our scientific laboratories only, but also in our workshops and factories where is carried on the manufacture of electric and telegraphic apparatus. Thus ohms, volts, amperes, coulombs, and microfarads are now common terms, and measurements in these units are commonly practised to within one per cent. of accuracy. It seems, indeed, as if the commercial requirements of the application of electricity to lighting and other uses of everyday life were destined to influence the higher region of scientific investigation with a second impulse not less important than that given thirty years ago by the requirements of submarine telegraphy.

[1] Abstract of lecture on "Electrical Units of Measurement," by Sir William Thomson, F.R.SS.L. and E., M.Inst.C.E., delivered on Thursday evening, May 3, 1883, at the Institution of Civil Engineers.

A first step toward the numerical reckoning of properties of matter is the discovery of a continuously varying action of some kind, and the means of observing and measuring it in terms of some arbitrary unit or scale division; while the second step is necessarily that of fixing on something absolutely definite as the unit of reckoning.

A short historical sketch was given of the development of scientific measurement, as applied to electricity and magnetism, from its beginning with Cavendish about 100 years ago, to the adoption of the absolute system of measurement by this country in 1869, at the instance of the British Association Committee on Electric Standards. The importance in this development of the originating works of Gauss and Weber was pointed out, as also of the eight years' labours of the British Association Committee. This Committee not only fairly launched the absolute system for general use, but also effected arrangements for the supply of standards for resistance coils, in terms of a unit, to be as nearly as possible 10^9 centimetres per second. This unit afterwards received the name of the ohm, which was adopted from a highly suggestive paper which had been communicated to the British Association in 1861 by Mr. Latimer Clark and Sir Charles Bright, in which some very valuable scientific methods and principles of electric measurement were given, and a system of nomenclature—ohmas, kilohmas, farads, kilofarads, volts, and kilovolts—now universally adopted with only unessential modification, was proposed for a complete system of interdependent electric units of measurement. At the International Conference for the Determination of Electrical Units held at Paris in 1882, the absolute system was accepted by France, Germany, and the other European countries; and Clark and Bright's nomenclature was adopted in principle and extended.

Gauss's principle of absolute measurement for magnetism and electricity is merely an extension of the astronomer's method of reckoning mass in terms of what may be called the universal gravitation unit of matter, and the reckoning of force, according to which the unit of force is that force which, acting on unit of mass for unit of time, generates a velocity equal to the unit of velocity. The universal-gravitation unit of mass is such a quantity of matter, that if two quantities, each equal to it, be placed at unit distance apart, the force between them is unity.

Here mass is defined in terms of force and space, and in the preceding definition force was defined in terms of mass, space, and time. Eliminating mass between the two, it will be found that any given force is numerically equal to the fourth power of the velocity with which any mass whatever must revolve round an equal mass, fixed at such a distance from it as to attract it with a force equal to the given force. And, eliminating force between the two primitive definitions of the universal gravitation system, it will be found that any given mass is numerically equal to the square of the velocity with which a free particle must move to revolve round it in a circle of any radius, multiplied by this radius. Thus, take a centimetre as the unit of length, and a mean solar second as the unit of time, and adopt 5·67 grammes per cubic centimetre as the mean density of the earth from Baily's repetition of Cavendish's experiment, and suppose the length of the seconds' pendulum to be 100 centimetres, and neglect the oblateness of the earth and the centrifugal force of its rotation (being at the equator only 1/289 of gravity), the result for the universal gravitation units of mass and force is respectively 15·36 French tons, and 15·36 megadynes, or 15·07 times the terrestrial surface-weight of a kilogram.

The ultimate principles of scientific measurement were illustrated by the ideal case of a traveller through the universe who has brought with him on his tour no weights, no measures, no watch or chronometer, nor any standard vibrator or spring balance, but merely Everett's units and constants, and a complete memory and understanding of its contents, and who desires to make for himself a metrical system agreeing with that which he left behind him on the earth. To recover his centimetre the readiest and most accurate way is to find how many wave-lengths of sodium light there are in the distance from bar to bar of a grating which he can engrave for himself on a piece of glass. How easily this is done, supposing the grating once made, was illustrated by a rapid experiment performed in the course of the lecture, without other apparatus than a little piece of glass with 250 fine parallel lines engraved on it by a diamond, and two candles and a measuring tape of unknown divisions of

length (only used to measure the *ratio* of the distance between the candles to the distance of the grating from either). The experiment showed the distance from centre to centre of consecutive bars of the grating to be 32 times the wave-length of yellow light. This being remembered to be $5\cdot89 \times 10^{-5}$ of a centimetre, it was concluded that the breadth of the space on which the 250 lines are engraved is 250. 32. 5·892. 10^{-5}, or ·4714 of a centimetre! According to the instrument-maker it is really ·5 of a centimetre! Five minutes spent on the experiment instead of one, and sodium flames behind fine slits, instead of open candles blowing about in the air might easily have given the result within one-half per cent. instead of $4\frac{1}{2}$ per cent. Thus the cosmic traveller can easily recover his centimetre and metre measure. To recover his unit of time is less easy. One way is to go through Foucault's experimental determination of the velocity of light.

But he must be imagined as electrically-minded; and he will certainly, therefore, think of "v," the number of electrostatic units in the electro-magnetic unit of electricity; but he will, probably, see his way better to doing what he wants by making for himself a Siemens' mercury unit (which he can do easily, now that he has his centimetre), and finding (by the British Association method, or Lorenz's with Lord Rayleigh's modification, or both), the velocity which measures its resistance in absolute measure. This velocity, as is known from Lord Rayleigh and Mrs. Sidgwick, is 9413 kilometres per mean solar second, and thus he finds, in mean solar seconds, the period of the vibrator, or arbitrary-unit chronometer, which he used in his experiments.

Still, even though this method might be chosen as the readiest and most accurate, according to present knowledge, of the fundamental data for recovering the mean solar second, the method by "v" is too interesting and too instructive in respect to elimination of properties of matter from our ultimate metrical foundations to be unconsidered. One very simple way of experimentally determining "v" is derivable from an important suggestion of Clark and Bright's paper, referred to above. Take a Leyden jar, or other condenser of moderate capacity (for example, in electrostatic measure, about 1000 centimetres), which must be accurately measured. Arrange a mechanism to charge it to an accurately measured potential of moderate amount (for example, in electrostatic measure, about 10 c.g.s., which is about 3000 volts), and discharge it through a galvanometer coil at frequent regular intervals (for example, ten times per second). This will give an intermittent current of known average strength (in the example, 10^5 electrostatic c.g.s., or about 1/300,000 c.g.s. electromagnetic, or 1/30,000 of an ampere), which is to be measured in electromagnetic measure by an ordinary galvanometer. The number found by dividing the electrostatic reckoning of the current, by the experimentally found electromagnetic reckoning of the same, is "v," in centimetres per the arbitrary unit of time, which the experimenter in search of the mean solar second has used in his electrostatic and electromagnetic details. The unit of mass which he has chosen, also arbitrarily, disappears from the resulting ratio It is to be hoped that before long "v" will be known within 1/10 per cent. At present it is only known that it does not *probably* differ 3 per cent. from $2\cdot9 \times 10^{10}$ centimetres per mean solar second. When it is known with satisfactory accuracy, an experimenter, provided with a centimetre measure, may, anywhere in the universe, rate his experimental chronometer to mean solar seconds by the mere electrostatic and electromagnetic operations described above, without any reference to the sun or other natural chronometer.

The remainder of the lecture was occupied with an explanation of the application of the absolute system in all branches of electric measurement, and the definition of the now well known practical units founded on it, called ohms, volts, farads, microfarads, amperes, coulombs, watts. The name mho, found by saying ohm to a phonograph and then turning the drum backwards, was suggested for a unit of conductivity, the reciprocal of resistance. The subdivision, millimho, will be exceedingly convenient for the designation of incandescent lamps.

The British Association unit has been found by Lord Rayleigh and Mrs. Sidgwick to be ·9868 of the true ohm (10^9 centimetres per second), which differs by only 1/50 per cent. from ·9870, the number derived from Joule's electrothermal measurements described in the British Association Committee's Report of 1867, with 772 Manchester foot-pounds taken as the dynamical equivalent of the thermal unit from the measurement described in his Royal Society paper of 1849, and confirmed by his fresh measurement of 20 years later, published in his last Royal Society paper on the subject.

It is satisfactory that, whether for interpreting old results, or for making resistance-coils anew, electricians may now safely use the British Association unit as ·9868, or the Siemens unit as ·9413, of the ohm defined as 10^9 centimetres per second.

U.S. NATIONAL ACADEMY OF SCIENCES[1]

THE annual meeting of this body was held in Washington during the last week, with an attendance of forty members. Scientific sessions were held on Tuesday, Wednesday, and Friday, in the large lecture-room of the National Museum, and business sessions on every day of the meeting.

Twenty-four foreign associates were elected as follows:—Astronomers: Prof. Otto von Struve, of the Imperial Observatory at Pulkowa, Russia; Prof. J. C. Adams, of Cambridge, Eng.; Prof. A. Auwers, Director of the Observatory at Berlin; and Prof. Theo. von Oppolzer, Director of the Observatory at Vienna. Mathematicians: Prof. Arthur Cayley, of the University of Cambridge, Eng.; Prof. J. J. Sylvester, of the Johns Hopkins University, Baltimore; and Prof. E. Bertrand, of Paris. Physicists: Prof. R. Clausius, of the University of Bonn; Baron H. von Helmholtz, Professor in the University of Berlin; Prof. Robert Kirchhoff, of the University of Berlin; Prof. G. G. Stokes, of the University of Cambridge, Eng.; and Sir William Thomson, Professor in the University of Glasgow. Chemists: Prof. J. B. Dumas, Secretary of the Academy of Sciences, Paris; and Professors M. Berthelot, Boussingault, Chevreul, and Würtz, all of Paris. Geologist: Freiherr von Richthofen, Professor in the University of Bonn, and President of the German Geographical Society. Botanists: Sir J. D. Hooker, Director of the Botanical Gardens at Kew, Eng.; Prof. A. de Candolle, of Geneva. Biologists: L. Pasteur, of Paris; Prof. T. H. Huxley, of London; Prof. R. von Virchow, of the University of Berlin; A. von Kölliker, Professor of Anatomy in the University of Würzburg. Prof. Struve, one of the newly elected foreign associates, who is on a visit to this country, was a regular attendant at the scientific sessions of the Academy, and read a paper.

In consequence of the death of Prof. W. B. Rogers, the President, it became necessary to elect his successor. On the first ballot, Prof. Wolcott Gibbs, of Cambridge, one of the founders of the Academy, was elected. He, however, firmly declined the honour, from a feeling, as he said, that he could not give the time necessary to the work. The Academy reluctantly acquiesced in the decision of Prof. Gibbs, and proceeded to a second ballot, when Prof. O. C. Marsh, of New Haven, the acting President, was elected by a handsome majority. The newly-elected President will hold office for six years.

The first act of the new President was to announce that he had received from Mrs. Mary A. Draper, widow of Prof. Henry Draper, the sum of six thousand dollars, accompanied by a deed of trust which fully specified the objects she had in view. He called upon Prof. Barker to explain the nature of the trust to the Academy. Prof. Barker first made some appropriate remarks, recalling Prof. Draper's interest in the Academy, and then read the deed, the substance of which is as follows:—The income of the trust is to be used "for the purpose of striking a gold medal which shall be called the 'Henry Draper Medal,' shall be of the value of two hundred dollars," and shall be awarded from time to time, but not oftener than once in two years, as a premium to any person in the United States or elsewhere who shall make an original investigation in astronomical physics, the results of which shall be deemed by the Academy of sufficient importance and benefit to science to merit such recognition. If at any time the income of the fund shall exceed the amount necessary for the striking of the medal, the surplus may be used in aid of investigations and work in astronomical physics to be made and carried on by a citizen of the United States.

The President appointed Messrs. G. F. Barker, W. Gibbs, S. Newcomb, A. W. Wright, and C. A. Young as a committee to have charge of the fund, to make rules to govern the award of the medal, and to suggest to the Academy for approval the names of those who may be considered worthy of the award.

The Treasurer announced that in accordance with the will of

[1] From *Science*, April 27.

the late Prof. James C. Watson the sum of about fourteen thousand dollars had been placed in his hands. When the estate is finally closed a further sum will be paid over to the Academy. The income of the Watson fund is to be used under the direction of three trustees—Messrs. J. E. Hilgard, S. Newcomb, and J. H. C. Coffin—for the purpose of aiding astronomical researches. In accordance with the recommendation of the trustees the Academy granted five hundred dollars from this fund towards defraying the expenses involved in observations of the total solar eclipse of May 6, 1883.

Later in the meeting Prof. Simon Newcomb of Washington was elected Vice-President, and Prof. Asaph Hall of Washington Home Secretary. Five new members were elected: Prof. A. Graham Bell of Washington, Dr. J. S. Billings, U.S.A., of the U.S. Army Medical Museum, Washington; G. K. Gilbert of the U.S. Geological Survey; H. B. Hill and C. L. Jackson, Professors of Chemistry in Harvard College. The whole number of members is now ninety-five.

On the afternoon of Thursday the Academy adjourned to take part by invitation in the ceremonies attending the unveiling of the statue of Prof. Henry in the grounds of the Smithsonian Institution. The time for these ceremonies was purposely fixed to coincide with that of the spring meeting of the Academy. Henry was preeminently a scientific man, and at the time of his death President of the Academy; and yet the members of the Academy were placed far down the line in the procession—after the Commissioners of the District of Columbia, and after officers of the army and navy. This fact must be regarded as evidence of a lack of appreciation of the relations existing between Henry and the Academy and of the true worth and dignity of science.

The exercises, which were in good taste, began with a short address by Chief Justice Waite. After this, at a signal, the covering was quickly drawn aside, instantly revealing the entire statue. Loud applause followed, those who were seated rose to their feet, and all hats were removed. The scene was highly impressive; and when the Philharmonic Society, accompanied by the full marine band, burst forth with Haydn's grand chorus, "The heavens are telling," the heart must have been a hardened one which did not experience a feeling of exaltation.

In the opinion of all, the statue is dignified and pleasing, and vividly calls to mind the honoured original. President Porter's oration, which was the principal event of the afternoon, was listened to with much interest. It dealt with the plain facts of the life of Henry, and was all that his best friends could have desired.

Among the pleasantest social features of the meeting was a reception given to the members of the Academy on Thursday evening by Prof. A. Graham Bell. There were present many well-known gentlemen, among them General Sherman, Chief Justice Waite, Senator Sherman, ex-Secretary Blaine, and the Japanese, Swedish, and Belgian ambassadors.

SCIENTIFIC SERIALS

Zeitschrift für wissenschaftliche Zoologie, Bd. xxxviii. Heft 1, February 20, 1883, contains:—On the vascular system and the imbibition of water in the Najadæ and Mytilidæ, by Dr. Hermann Griesbach (Pl. 1).—Researches among the Protozoa, by Dr. A. Gruber (Plates 2 to 4); describes and figures several new genera and species.—On the origin of the saliva (*Futter saft*) and the salivary glands in the bee, together with an appendix on their olfactory organ, by Dr. P. Schiemenz (Plates 5 to 7).—On the development of the red blood corpuscles, by Dr. W. Feuerstack (woodcuts).—Candid reply to my critics in the matter of the "Brain of Fishes," by G. Futsch.

Proceedings of the St. Petersburg Society of Natural History, Vol. xiii. Part 1, for 1882, contains: On the archæology of Russia, by Count Tivatkov (the Stone Period).—Notes of a journey on the Dnieper in 1844, by Dr. Kessler.—On *Capra caucasica*, Güld., by H. Dinnik.—Darwinism from the point of view of universal physical science, by A. Beketov.—A monograph of the Mysidæ to be found in Russia (Marine, Lacustrine, and Fluviatile), by Voldemaro Czerniavsky, fasc. 2. All the above articles are in Russian except the last, which is in Latin, and it is illustrated by four lithographic plates.

Journal of the Russian Chemical and Physical Society, vol. xv. fascicule 3.—On the hydrocarbon $C_{12}H_{20}$ obtained from the allyl dimethyl carbinol, by Prof. A. Zaytseff and W. Nicolsky.—On the hydrocarbon $C_{10}H_{18}$ obtained from the allyl dipropyl carbinol, by S. Reformatsky. It is a colourless liquid boiling at about 158° Celsius, insoluble in water, and easily soluble in alcohol and ether. It rapidly absorbs the oxygen of the air; density 0·787 at 0°, 0·774 at 16°, and 0·770 at 21°.—Chemical analysis of Kieff clays, by S. Bogdanoff. The white clay contains 96 per cent. of kaolins; the loess contains 83·5 per cent. of quartz, felspar, mica, and other silicates, 5·38 of kaolin, and 6·73 of carbonate of lime.—On the diisooctyl, by A. Alechin.—On the composition of the water which accompanies the naphtha and is discharged by mud-volcanoes of the Government of Tiflis, by A. Potylitzin (second paper).—An elementary demonstration of the pendulum-formula, and on a differential aërial calorimeter, by W. Preobrajensky.

THE *Archives des Sciences Physiques et Naturelles* for February, 1883, contains papers by C. E. Guillaume on electrolytic condensers; by Emile Yung, on the errors of the senses, a contribution to the study of illusions and hallucinations; by Ernest Favre, on the Geological Survey of Switzerland for 1882, concluded in the March number. To the latter C. de Candolle sends an interesting essay on the ripple marks formed on the surface of sands under water, and on other analogous phenomena.

THE *Journal de Physique théorique et appliquée* for March contains papers by Ph. Gilbert, on the experiments best suited for demonstrating the rotation of the earth; by G. Lippmann, on Helmholtz's theory of double electric layers as applied to electro capillary phenomena; by H. Pellat, on the same subject; by A. Rosenstiehl, on the definition of complementary colours; by Ch. Cros and Aug. Vergeraud, on a direct positive photographic paper.

SOCIETIES AND ACADEMIES

LONDON

Royal Society, March 15.—"On the Changes which take place in the Deviations of the Standard Compass in the Iron Armour-plated, Iron, and Composite-built Ships of the Royal Navy on a considerable change of Magnetic Latitude." By Staff-Commander E. W. Creak, R.N., of the Admiralty Compass Department. Communicated by Capt. Sir F. J. Evans, R.N., K.C.B., F.R.S., Hydrographer of the Admiralty.

The period comprised between the years 1855–68 was one of active research into the magnetic character of the armour-plated and other ships of the Royal Navy and iron ships of the Mercantile Navy.

Among other contributions to this subject a paper by F. J. Evans, Staff-Commander R.N., F.R.S., and Archibald Smith, F.R.S., was read before the Royal Society in March 1865, relating to the armour-plated ships of the Royal Navy, and containing the first published results of the system of observation and analysis of the deviation of the compass established four years previously.

From lack of observations in widely different magnetic latitudes the authors of that paper were unable to define the proportions of the semicircular deviations arising from vertical induction in soft iron and that arising from permanent or sub-permanent magnetism in hard iron.

During the last fifteen years vessels of all classes—except turret ships—have visited places of high southern magnetic inclination or dip, and the analysis of the deviations of their standard compasses has been made, showing the constants of hard and soft iron producing semicircular deviation.

The constants for soft iron provide a means of predicting probable changes of deviation on change of magnetic latitude for certain vessels of the following classes, and others of similar construction.

1. Iron armour-plated ships.
2. Iron cased with wood.
3. Iron troopships.
4. Iron and steel cased with wood.
5. Composite-built vessels.
6. Wooden ships with iron beams and vertical bulkheads.

These vessels were all in a state of magnetic stability previous to the observations which have been discussed, and their compasses have had the semicircular deviation reduced to small values, or corrected, in England by permanent bar magnets.

This correction may be considered as the introduction of a permanent magnetic force acting independently, and in opposition to the magnetic forces of the ship proceeding from hard iron.

It is now proposed to consider the effects of a change of magnetic latitude on the component parts of the deviation.

Semicircular Deviation

On semicircular deviation from fore and aft forces, time has but little effect, and the greater part of it is due to permanent magnetism in hard iron which may be reduced to zero for all latitudes, by a permanent magnet.

A second but small part of this semicircular deviation proceeds from sub-permanent magnetism in hard iron. It is subject to alterations slowly by time, from concussion, and from the ship remaining in a constant position with respect to the magnetic meridian for several days, and is more intensely affected by a combination of the two latter causes.

Deviations from sub-permanent magnetism which have temporarily altered in value as described, return slowly to their original value on removal of the inducing cause.

The principal cause of change in the semicircular deviation on change of magnetic latitude, in corrected compasses, arises from vertical induction in soft iron, which changes directly as the tangent of the dip.

In standard compasses judiciously placed with regard to surrounding iron this element of change is small and similar in value for similar classes of ships.

With very few exceptions, nearly the whole of the semicircular deviation from transverse forces is due to permanent magnetism in hard iron subject to the same laws as that proceeding from fore and aft forces.

In the exceptional cases alluded to there is a small part due to vertical induction in soft iron, changing directly as the tangent of the dip.

Quadrantal Deviation

This deviation is caused by induction in horizontal soft iron symmetrically placed, and it does not change with a change of magnetic latitude. Time alone appears to cause a gradual change in its value during the first two or three years after the ship is launched, when it becomes nearly permanent.

The diminution of the mean directive force of the needle which is common to all modern vessels of war, improves slowly at first by lapse of time, and finally assumes a permanent value.

Relative Proportions of Hard and Soft Iron

It has been found that the relative proportions of the hard and soft iron affecting the standard compasses of twenty-five vessels examined differ considerably, even in ships of similar construction.

This difference may be accounted for by the compasses not being placed in the same relative position in the ships, considered as magnets of various forms and containing numerous iron bodies introduced during equipment.

General Conclusions

The following general conclusions have special reference to the standard compass positions in the six classes of vessels previously mentioned.

1. A large proportion of the semicircular deviation is due to permanent magnetism in hard iron.

2. A large proportion of the semicircular deviation may be reduced to zero, or corrected, for all magnetic latitudes, by fixing a hard steel bar magnet or magnets in the compass pillar, in opposition to, and of equal force to, the forces producing that deviation.

3. A very small proportion of the semicircular deviation is due to sub-permanent magnetism, which diminishes slowly by lapse of time.

4. The sub-permanent magnetism produces deviation in the same direction as the permanent magnetism in hard iron, except when temporarily disturbed (1) by the ship's remaining in a constant position with respect to the magnetic meridian for several days, (2) by concussion, or (3) by both combined, when the disturbance is intensified.

5. To ascertain the full value of changes in the sub-permanent magnetism, observations should be taken immediately on the removal of the inducing cause.

6. In the usual place of the standard compass the deviation caused by transient vertical induction in soft iron is small, and of the same value (nearly) for ships of similar construction.

7. The preceding conclusions point to the conditions which should govern the selection of a suitable position for the standard compass with regard to surrounding iron in the ship.

Anthropological Institute, April 24.—Prof. W. H. Flower, F.R.S., president, in the chair.—The election of Mr. C. Roberts, F.R.C.S., was announced.—Mr. W. M. Flinders Petrie read a paper on the mechanical methods of the Egyptians. The author exhibited several specimens of ancient Egyptian work, and described the methods by which he believed them to have been produced.—Mr. F. C. J. Spurrell read a paper on some palæolithic knapping tools and modes of using them.

May 8.—Prof. W. H. Flower, F.R.S., president, in the chair.—Mr. Frederick Bonney read a paper on some customs of the aborigines of the River Darling, New South Wales. The tribes with which the author was most familiar are called Bungy-arlee and Parkungi. They inhabit a district within lat. 29°–34°. S., long. 141°–146° E. The country in its natural state was incapable of supporting a large population, being subject to protracted droughts, during which both food and water were scarce. There is a similarity in the typical features of all the Australian aborigines, but to a close observer each tribe has its own peculiarities. Though ugly and unprepossessing in appearance, they are most kind, gentle, and of quite average intelligence and morality. The aborigines of Australia are often spoken of as the lowest type of humanity, but the author considered this to be a libel on the whole of them, and was positive it is so as regards the tribes he knows best. Mr. Bonney then proceeded to give a description of the life-history of the above-mentioned tribes.—Lieut.-Col. H. H. Godwin-Austen, F.R.S., read a paper on the discovery of some worked flints, cores, and flakes from Blackheath, near Chilworth and Bramley, Surrey.—A paper by Admiral F. S. Tremlett, F.G.S., was read, on stone circles in Brittany, in which the author described three circles discovered by the late Mr. James Milne, in the commune of Carnac; they had presumably been places for cremating the dead, and also for depositing the urns; the greater part of the latter were found inclosed in cists of quartz covered over by a slab of schist, neither of which are to be found in the district.—Mr. W. Galloway exhibited a skull and a number of rubbed bones and other implements from the islands of Oronsay and Colonsay, forming part of a large collection exhibited by him in the Great International Fisheries Exhibition.

Physical Society, May 12.—Prof. Clifton in the chair.—New Member, Mr. A. W. Soward.—Mr. Woodward described an experiment illustrating motion produced by diffusion. A porous reservoir of clay containing air was suspended from one end of a weighted balance beam. A glass tube projected from it below and dipped into a vessel of water. A jet of hydrogen gas was allowed to play on the outside of the reservoir and the balance beam began to oscillate. This is an adaptation of Graham's well-known experiment, and is in fact a diffusion engine. Prof. Adams explained the action by the variation of pressure in the reservoir set up by diffusion.—Mr. W. Lant Carpenter read a paper on some uses of a new projection lantern. This lantern, of German make, is applied by Mr. Paterson, and is simple in construction, cheap, and gives a good image visible to a large audience. It can be used with a three-wick oil lamp or the limelight. Mr. Carpenter showed a number of objects on the screen. Mr. Lecky and Mr. Woodward offered some remarks, the latter deprecating a too frequent use of projection with students.—Dr. C. R. Alder Wright read a paper on the electromotive force of Clark's mercurous sulphate cell and the work done during electrolysis. He described the best mode of constructing Clark's standard cell. According to numerous tests, these cells vary in E.M.F. about 0·2 per cent. + or − among themselves. A cell properly made will keep its value for about two years. It is of great importance that the cell should not be worked or the current reversed through it, otherwise it may permanently deteriorate. The extraction of air from the paste is not very essential, and boiling it is unnecessary. It is more important that the solutions of zinc sulphate should be saturated. Dr. Wright described a cell in vacuum which is a good standard. He found the E.M.F. to vary 0·4 per cent. between 0° and 100° C. With regard to the work done in a cell, among other interesting deductions, he found that in a secondary battery the larger the plates the greater the economy. In the electrolysis of water the greater the surface condensing power of the electrodes for gas the less difference of potential is required to decompose the water. Thus with platinum electrodes a lower E.M.F. serves for the electrolysis than with gold electrodes.—Prof. Foster then took the chair, and Prof. Clifton read a paper on a complete determination of a double convex lens by lineal

measurements on the optical bench. This was a method (somewhat similar to that of Mr. Boys, previously described to the Society) for determining the four quantities of a lens on the bench by lineal measures, and without the use of the spherometer and prism. Experiments showed that it was about as accurate as the spherometer method.

Edinburgh

Royal Society, May 7.—Prof. Maclagan, vice-president, in the chair.—By request of the Council Prof. James Geikie gave an address on recent advances in the Pleistocene geology of Europe. The characteristic deposits of this period, which embraces the Palæolithic age of the antiquarians, were described in considerable detail—the terminal and ground moraines and other glacial remains, the fluviatile and lacustrine formations, and the cave deposits. The limits were indicated of the great Scandinavian ice-sheet, which pushed itself southward over North Germany and over the watershed of Central Russia, and westward across the German Ocean towards our islands, thereby modifying the trend of the native ice-streams that have left their traces all over our hills and round our coasts. As an indication of the great power of this agent it was mentioned that some portions of the brown-coal beds of Saxony which have been long worked are really not *in situ*, but have been pushed out of place by the ice-sheet. In describing the fluviatile deposits Prof. Geikie drew attention to a suggestion made by Darwin, that frozen snow accumulating in the valleys below the glacier limits might easily act as barriers and give rise to extensive flooding. The fauna and flora and the evidence of the interglacial beds were then touched upon, and the address ended with a general summary of results with special reference to the climatic peculiarities of the Pleistocene period. It thus appeared that Europe was subjected to great climatic changes, severe glacial periods alternating with times of peculiar equable climate in which temperate flora and fauna flourished side by side with forms which are now met with only in southern regions.

Sydney

Linnean Society of New South Wales, March 28.—Rev. J. E. Tenison-Woods, F.L.S., vice-president, in the chair.—The following papers were read:—Occasional notes on plants indigenous in the immediate neighbourhood of Sydney (No. 3), by Edwin Haviland. This paper refers chiefly to the genus *Lobelia*, its mode of fertilisation, and its domestication.—On tooth-marked bones of extinct marsupials, by Chas. W. de Vis, B.A., A large proportion of fossil marsupial bones from the Darling Downs, recently examined by Mr. de Vis, are considered by him to show more or less decided traces of the action of the teeth of carnivorous animals. The tooth-marks are ascribed to the agency partly of the native dog, partly of the *Thylacoleo*, and partly of an extinct species of *Sarcophilus* which was identified by a portion of a tibia.—On *Brachalletes palmeri*, an extinct marsupial, by Chas. W. de Vis, B.A. A femur from the Darling Downs differs so markedly from that of *Macropus* and *Halmaturus* in the less prominent character of the great trochanter that it is considered to belong to a new generic type, proposed to be named *Brachalletes*.—On the habits of the "Mallee hen" (*Leipoa ocellata*), by K. H. Bennett. This gives an interesting and detailed account from the author's own observation of the nidification and general habits of this very curious bird.—Mr. Macleay exhibited a specimen of *Dendrolagus dorianus*, a new species of Tree Kangaroo from Mount Owen Stanley, New Guinea, described by Mr. E. P. Ramsay at the January meeting of the Society. He pointed out that the hair on the body all turned the wrong way.

Berlin

Physiological Society, April 13.—Prof. du Bois Reymond spoke about a series of electrophysiological investigations which he began at the same time as his "Investigations in Animal Electricity," which have long since been incorporated in science, now forty years ago, and about which he has as yet not published anything, viz., about the secondary electromotor phenomena of muscles, nerves, and electric organs. These latter are distinguished from primary electromotor phenomena of nerves and muscles by the fact that the latter appear in quiescent organs and take place without being directly influenced by an external electric current, whereas the former appear only as a consequence of an extrinsic electrical current, and consequently are connected with the polarisation appearances in electrolytical conductors. When a current is led through a fluid electrolyte by means of metallic electrodes, a reverse (negative) polarisation current is, as is well known, produced between the electrodes by the accumulation of ions on the anode and cathode. In the year 1836 Peltier described a similar negative (in direction opposed to principal current) polarisation in masses of frogs' limbs through which an electrical current was being passed, and explained it in the same way by the development of ions on the electrodes. When Prof. du Bois Reymond repeated this experiment in the beginning of the forties, he found that an electromotive force was active not only at the electrodes, but that each piece of the preparation through which the current was passing had a negative electromotive reaction, and showed an opposite current to the polarising one in a galvanometer that was applied. On further study of this phenomenon, he found this "inner" polarisation in every porous conductor, which is soaked with a readily conducting electrolyte, and it was in all cases negative; on the other hand an outer positive polarisation exhibited itself on the line of contact of dissimilar electrolytes, *e.g.* when the current was led through a pad soaked with water into a salt solution. Fresh animal tissues of the most different kinds, when a current was led through them between pads soaked in common salt, accordingly showed an outer positive and an inner negative polarisation. Further, the lecturer studied an outer and an inner secondary (called forth by the current) resistance, of which the former was at least partially accounted for by the cataphorical action of the current. When afterwards (*i.e.* after the determination of the above-mentioned physical phenomena) the inner polarisation was studied on living muscles, secondary electromotor appearances of such irregularity and complexity manifested themselves that it was only after laborious investigations that were extended over many years that the simple law that the phenomena obey was discovered. It was discovered that when a current was passed through a muscle the inner polarisations might be positive as well as negative, that they depend on the density and length of duration of the polarising current, and that each of these polarisations can be altered in a different manner by these two factors. If the densities and duration of action of the primary current are properly graduated, the phenomena follow the following law:—With very weak polarising currents the inner polarisation is negative, and increases up to a certain limit with the duration of the current; with somewhat stronger currents, the inner polarisation is at first positive, but soon passes over into the negative, which goes on increasing with the duration of the current; with still stronger currents, the initial positive inner polarisation becomes stronger and longer lasting, and then again becomes negative with the longer duration of the primary current. If the density of the polarising current increases still more, the initial positive current becomes weaker and weaker, and finally disappears altogether, and gives way to a polarisation that is negative from the beginning. Accordingly there exists in the interpolar portion of a muscle that is traversed by a current, after a certain limit has been exceeded, a positive inner polarisation, which in a short time is replaced by a negative polarisation, and the deduction from these phenomena is that both secondary electromotive forces—those with the same and with opposite directions—are present in the portion of muscle traversed by the electrical current. These electromotive forces manifest themselves alternately, the predominance of the one and the other being conditioned by the several dependence of each upon the density and duration of the primary current. This indication of a positive inner polarisation, *i.e.* of secondary electromotor forces, which occasion a current in the same direction as the primary current, is a fact of fundamental import in the theory of animal electricity. The positive polarisation proved itself to be dependent upon the direction of the primary current, since it was stronger in the upper half of the muscle when the direction of the current was from below upwards, whereas it was stronger in the lower half with a descending current; furthermore it manifested itself in living muscles only, whereas the negative polarisation occurred also in muscles that had been boiled or otherwise killed; finally, the positive polarisation was less strong in active than in quiescent muscles. At the end of the fifties the lecturer had also succeeded in demonstrating a positive inner polarisation in nerves; it showed the same regularity as was afterwards, with finer appliances, quantitatively estimated in muscles; that is to say, with small current-densities a negative polarisation only was manifested; with greater current-densities and very short duration of closing a purely positive polarisation was manifested,

which passed over into a negative polarisation with the longer duration of the primary current. Here also the different manifestations of the nerve polarisation led, as in muscles, to the recognition of two simultaneous electromotive forces, which behave differently to the intensity and duration of the primary current. And as in muscle the direction of the primary current influenced the strength of the positive polarisation, similarly in nerves the direction had an influence upon the positive polarisation predominating in the motor nerve-roots when the current was a descending one, and conversely in the sensory nerve-roots when the current was an ascending one; consequently both times the direction of the physiological nerve-wave predominated. Finally, Prof. du Bois Reymond gave an account of his experiments by which he has demonstrated quite analogous secondary electromotor phenomena in the electric organs of the electric fish (Malapterurus). In the theoretical discussion of the results of these experiments that were carried on for so many years the lecturer pointed out in conclusion that the inner polarisation, the positive polarisation in particular, could scarcely be otherwise explained except by the hypothesis that in the above-mentioned organs (the muscles, nerves, and electric organs) electromotor molecules preexisted during life, which, being turned by the polarising current, became the occasioned causes of the electromotor phenomena.—Prof. Rosenthal of Erlangen spoke about the experiments he had made to ascertain the electric conductivity of living tissues. He dwelt on the difficulty of exactly measuring its amount, which he could only overcome by using alternating currents, of which, by the help of a particular apparatus, currents of one direction only acted upon the galvanometer of the Wheatstone's bridge. On the living man he found the resistance of the epidermis so great that he regards it as an excellent insulator which permits the electrical current to pass through to the deeper organs only through the medium of the canals (the pores) that ramify through it and that are filled with fluid. The measurements of the conductivity of living animal tissues are not yet quite completed.

PARIS

Academy of Sciences, May 7.—M. Blanchard in the chair.—M. Loewy explained his new method for determining at any moment the relative position of the instrumental equator in relation to the real equator. This method is analogous to that already given for right ascensions, being founded on the observation of the stars near the pole, and on the variations in the relations of the coordinates due to the deflection of the instrument. M. Loewy demonstrates mathematically that his plan combines all the theoretical and practical conditions required for the complete solution of the problem. It is based on the theorem here demonstrated that when the track described by a star in apparent distance from the pole coincides with its distance in relation to the instrumental plane, the angle may be exactly determined which is formed by the terrestrial axis with the line of the instrumental poles, by means of the variation observed between the apparent polar distance and the distance in relation to the instrumental plane. The method is independent of any possible variations in the state of the instrument during a period of twelve hours, and it excludes the cause of systematic error due to refraction. It is moreover capable of extreme accuracy, which, by multiplying the points, may be carried as far as is desirable.—M. Tresca submitted some remarks on the observations made last year by Prof. Lemström in Lapland on various circumstances connected with the phenomenon of the aurora borealis, which have been reported in NATURE.—M. Th. du Moncel presented a paper by M. E. Semmola on the annual variation of temperature in the waters of the Bay of Naples, showing the results of observations made during the summer of 1879 and January, 1880, with a Negretti and Zambra thermometer. The observations were generally taken during calm weather between the hours of 11 a.m. and 3 p.m., in depths of 30 or 40 feet, and at some distance from the coast. They showed that on the whole the Bay of Naples is only a few degrees warmer than the Mediterranean, which, from the observations made in the August of 1870 by the English expedition under Prof. Carpenter, was found to be 25° C. at the surface, 15°·5 at a depth of 180 feet, 14° at 230, 13° at 620, and nearly the same down to 10,000 feet. In the bay the temperature varied from 13° on the surface in winter to 27° in summer, showing a mean of about 20°, or 3° higher than the city of Naples. This result also agrees with the mean annual temperature of the Mediterranean, which, according to Mohn, lies between 16° and 19° in the west, and 21°–23° in the east.—Other papers were contributed by M. Lecoq de Boisbaudran on the extremely sensitive character of salts of iridium, rendering them most useful in detecting the presence of the smallest particles of iridium in compound substances; by G. A. Hirn, continuing the *résumé* of the meteorological observations made during 1882 at four points of the Upper Rhine and Vosges highlands; by Th. Schwedoff, on the form of the great comet of September, 1882, with two cuts showing its appearance on October 12 at Lyons, and on October 17 and November 7 at Odessa; by E. de Jonquières, on the identities presented by the reductions belonging respectively to the two "modes" of continuous periodical fractions. By "the two modes" of continuous fractions the author understands, on the one hand the ordinary continuous fractions ("first mode"), on the other those in which the numerators differ from unity ("second mode").—Papers were also submitted by M. Vieille, on the specific heats of some gases at high temperatures; by C. Resio, on the electrodynamograph, an instrument constructed for recording the work executed by machinery; by J. A. Le Bel, on the amylic alcohol developed in alcoholic fermentation; by M. Gonnard, on the staurolites and regular groupings of the felspar crystals in the siliceous porphyry of Four-la Brouque, near Issoire (Puy-de-Dôme); by J. Thoulet, on the elasticity of rocks and minerals; by P. Mégnin, on the direct reproduction of tænia in the intestines of the dog and man; by B. de Chancourtois, on a common meridian and measurement of time in view of the universal adoption of a complete decimal system, with a planisphere showing two proposed initial meridians passing through Behring Strait and the Azores; by Ch. Contejean, on some special cases of distribution in the Italian flora.

HUMAN FACULTY AND ITS DEVELOPMENT

Inquiries into Human Faculty and its Development. By Francis Galton, F.R.S. (London: Macmillan and Co., 1883.)

AMONG all his anthropological brethren Mr. Francis Galton has no competitor in regard to the variety and versatility of his researches. So various and versatile, indeed, have these researches been, that, with the exception of "Hereditary Genius" and "English Men of Science, their Nature and Nurture," we have become accustomed to regard them as disconnected pieces of work, which from time to time were thrown off like sparks from the flame of an active mind. But in the present volume he has collected in one series most of the investigations which he has separately published during the last ten years, and this collection when read in the light of a considerable amount of additional matter, clearly shows that the sundry investigations which were separately published were not separately conceived, but have throughout been united by the bond of a common object. This object, as the title of the book indicates, is that of inquiry into Human Faculty and its Development. And it is evident, when this fundamental note is supplied, that it serves to join not only the researches contained in the present volume, but also those of its above-named predecessors, into one harmony or design.

But although there is one harmony pervading this work, the changes of theme are so numerous that we shall not be able to touch upon them all, and must therefore restrict ourselves to considering the more important.

The book begins with an essay on "Variety of Human Nature," as to features, bodily qualities, energy, sensitivity, special senses, &c. In the course of this chapter the leading results of the author's well-known investigations on composite portraiture are brought in, the audibility of high notes in different individuals, as well as in different species of animals, &c. Next there follows a chapter on "Anthropomorphic Registers," which is mainly directed to showing the desirability of keeping family records of the anthropometry of children until they are old enough to continue the records for themselves. To facilitate this process—which he deems to be one of much practical importance in view of all that is now known touching the potency of hereditary influences—Mr. Galton urges that anthropometric laboratories should be established where all the needful periodic portraiture and other observations on the life-history of children should be made and preserved on the payment of small fees by the parents. Without such systematic observation any one may pass through life without knowing that he presents so strongly marked a peculiarity as that of colour-blindness; while the benefit to the race, a few generations hence, of a large mass of statistics of such consecutive anthropometry of numerous families would probably be of the utmost value. Indeed this suggestion as to anthropometric laboratories may be taken as the foundation of Mr. Galton's proposed science of "eugenics," to a tracing of the main principles of which his work on "Human Faculty" is chiefly concerned.

After a chapter on "Statistical Methods," we come to a consideration of "Character." So far as sex is concerned, "one notable peculiarity in the character of the woman is that she is capricious and coy, and has less straightforwardness than the man . . . and there can be little doubt as to the origin of the peculiarity. . . . The willy-nilly disposition of the female in matters of love is as apparent in the butterfly as in the man, and must have been continuously favoured from the earliest stages of animal evolution down to the present time. It is the factor in the great theory of sexual selection that corresponds to the insistence and directness of the male. Coyness and caprice have in consequence become a heritage of the sex, together with a cohort of allied weaknesses and petty deceits, that men have come to think venial and even amiable in women, but which they would not tolerate among themselves."

The type of character which leads to criminality is next discussed, and is shown by statistics to be strongly inherited. After a few pages on the allied topic of insanity, Mr. Galton passes on to consider the gregarious and slavish instincts, where he shows from first-hand observations on wild or but partly domesticated animals the immense utility of these instincts. We ourselves inherit from our savage ancestry instincts of the same kind, and thus it is that the less intellectually developed among us are so prone to submit ourselves, like sheep, to the guidance of a leader, and even to the tyranny of a despot.

Passing on to intellectual differences, a long and interesting account is given of mental imagery, the main points of which are already known to the readers of NATURE. It is remarkable that men of science, and of hard thinking generally, are for the most part totally deficient in this faculty. The discussion of mental imagery naturally leads to the resemblance which Mr. Galton has previously pointed out between his composite photographs and general ideas; each alike are "generic images," and in many matters of detail the analogy, or, as we should prefer to call it, the illustration, holds good.

Next we come to a chapter on Psychometric Experiments, which is devoted to an account of interesting experiments on the association of ideas. The influence of early association and sentiment is shown by these experiments, and by considerations drawn from them, to be much greater than is generally supposed.

One of the most interesting chapters in the book is that which next follows on the History of Twins. It will be remembered that the main fact elicited by this inquiry is that nature counts for much more than nurture; for it is shown that "instances exist of an apparently thorough similarity of nature, in which such difference of external circumstances as may be consistent with the ordinary conditions of the same social rank and country do not create dissimilarity. . . . The twins who closely resembled each other in childhood and early youth, and were reared under not very dissimilar conditions, either grow unlike through the development of natural characteristics which had lain dormant at first, or else they continue their lives, keeping time like two watches, hardly to be thrown out of accord except by some physical jar. . . . The effect of illness, as shown by these replies, is great, and well deserves further consideration. It appears that the constitution of youth is not so elastic as we are apt to think; but that an attack, say of scarlet fever, leaves a permanent

F

mark, easily to be measured by the present method of comparison."

The essay which follows on the "Domestication of Animals" is not so interesting, because not so original, as the rest of the book; all its points are obvious to any one who has thought about the subject at all.

A consideration of the Possibilities of Theocratic Intervention next leads the way to a reappearance of the author's paper on the Objective Efficacy of Prayer. Here the logic is unexceptionable as far as it goes, but it is not such as to leave no loophole of escape for orthodox belief. The argument is that if prayer is of any avail in an objective sense, it ought to admit of being shown by the statistical method to be so. But, as the present writer pointed out nine years ago when considering this essay, the statistical method applied to such a case is of doubtful validity. To show this we may quote one paragraph from our previous criticism:—

"What, then, is the whole state of the case? To illustrate it most fairly, we shall take the strongest of the examples supplied by Mr. Galton, viz. that of the Clergy. As Mr. Galton truly observes, in no other class are we so likely to obtain men of Prayer. Suppose, then, for the sake of calculation, that one-half of the clergy are sufficiently prayerful to admit of their petitions influencing the course of physical phenomena. Next, let us suppose that one-half of their successful petitions for physical benefits are offered on behalf of individuals other than themselves: this is equivalent to reducing the number of the prayerful clergy to one-fourth. Here we ought to add that in whatever degree this section of successful prayers may influence the prayerless classes of the community, in that degree is the comparison still further vitiated. Neglecting this point, however, let us lastly suppose that one-half of the petitions for physical benefits offered on the petitioner's own behoof are answered by physical benefits of some other kind; . . . this is equivalent to reducing the original number to one-eighth. Now I do not think any of these suppositions are extravagant. Let us see the result of applying them to Mr. Galton's tables. According to these tables, the clergy as a class live, on an average, two years longer than men of any of the other classes quoted, notwithstanding we are repeatedly told that, as a class, they are the most poorly constitutioned of all. Now, neglecting the last-mentioned point, and also the fact that all clergymen do not pray for long lives; still, even on the above data, an average of two additional years over all the clergy allows, when concentrated into one-eighth of their number, an average of sixteen additional years of life to every pious divine. Of course this illustration is not adduced in order to prove that prayer has in this case been observably effectual. The greater length of life enjoyed by the clergy may be conceded due to the cause assigned by Mr. Galton—viz. the repose of a country life—or to any other cause, without in any way affecting the present argument. All we are engaged in showing is that the statistical method is not a trustworthy instrument wherewith to gauge the physical efficacy of prayer; and the above illustration has been adduced to show that even if the petitions of the pious clergy for lengthened days were somewhat more effectual than those of Hezekiah, statistics would still be so far unable to take cognisance of the fact that the observable average increase of two years over the entire body of the clergy might reasonably be attributed to other causes. Yet length of days is perhaps the most conspicuous, and therefore the most easily tabulated, of all physical benefits for which it is possible to pray."[1]

After some well considered remarks on Enthusiasm, or "to what degree the strong subjective views of the pious are trustworthy," the book begins to draw towards its final object, which is virtually that of marking out the lines of what may appropriately be called a new religion. We have of late had so many manufactures of this kind that the market is somewhat glutted, and therefore it is very doubtful how far this new supply will meet with an appropriate demand; but we can safely recommend Mr. Galton's wares to all who deal in such commodities as the best which have hitherto been turned out. They are the best because the materials of their composition are honesty and common sense, without admixture with folly or metaphor. He says: "We may not unreasonably profess faith in a common and mysterious whole, and of the laborious advance, under many restrictions, of that infinitely small part of it which falls under our observation, but which is in itself enormously large, and behind which lies the awful mystery of all existence." Having, then, this faith in the seen, and observing that, whatever the far-off divine event may be to which the whole creation moves, the whole creation is certainly moving in an upward course of evolution, Mr. Galton submits that man has now reached a level of intelligence which should enable him, not merely to know these things, but to do them. He ought to "awake to a fuller knowledge of his relatively great position," and begin to regard it as his high prerogative to cooperate with the unknown Worker in promoting the great work. He may infer the course that evolution is bound to pursue, and might therefore "devote his modicum of power, intelligence, and kindly feeling to render its future progress less slow and painful. Man has already furthered evolution very considerably, half unconsciously and for his own personal advantages; but he has not yet risen to the conviction that it is his religious duty to do so deliberately and systematically."

Several directions in which such assistance might be yielded are pointed out in the concluding pages of the book, especially in the way of "eugenics"; and there can be no question that, if the idea of promoting evolution could become generally, or even largely, invested with a feeling of obligation, the prospects of the race would be greatly brightened. The most important field of human activity under such circumstances would obviously be that of improving the race by selection, and Mr. Galton throws out several well considered suggestions as to the way in which this might be done without violating so precious a product of evolution as the moral sense, or seriously interfering in any other particular with the ordinary usages of civilised life.

We have said enough to show that in respect of its matter "Human Faculty" is an unusually interesting work; but we should not do it justice were we to conclude this brief notice without alluding also to its manner or style. There is a strand of humour woven through the serious texture of the whole, which, together with the ingenious cast of thought and the ingenuous cast of feeling, affords a most pleasing and instructive study, unconsciously presented, of the nature and nurture of an English man of science.

GEORGE J. ROMANES

[1] Burney Prize Essay on "Christian Prayer and General Laws," pp. 265-6 (Macmillan and Co., 1873), where other and more important considerations against this application of the statistical method are given. [I may observe that this essay was written on a thesis which was set by the Vice-Chancellor of Cambridge, and I still think that, upon its given basis of Christian belief, all the more important of its arguments hold, both as regards prayer and miracles.—G. J. R.]

THE GEOLOGICAL HISTORY OF BRITAIN

Contributions to the Physical History of the British Isles; with a Dissertation on the Origin of Western Europe and of the Atlantic Ocean. Illustrated by 27 Coloured Maps. By Edward Hull, F.R.S., &c. (London: Stanford, 1882.)

IF Geology may be correctly described as a history of the earth, then a geologist is in the first place and essentially a historian. His function is to trace back the gradual growth of the world, organic as well as inorganic, and to show through what successive stages the present conditions of geography and of life have been reached. His materials, like those of the historian of human progress, become fewer and less reliable in proportion to their antiquity. More and more as he pilots his way into the records of the remoter past is he driven to piece together their evidence with conjecture, until at last evidence of every kind fails him, and he is reduced to mere speculation. There is undoubtedly a strong temptation to minds of a particular order to indulge in wide excursions into the unknown realms of primeval cosmogony. The fewer the facts that may serve as guide-posts the greater the scope for the fancy. So long as the picture does not appear to outrage our established conceptions of physical law its enthusiastic limner considers himself within the safe limits of fact or, at least, of legitimate inference. He does not stop to consider whether his restoration may not in itself be flagrantly improbable, or whether enough may not be already known on the subject to show that it is quite untenable. In this way much harm has been done to the progress of sound geology.

The attempt to restore former aspects of the globe, or at least of different areas of its surface, may be made with fair measure of success up to a certain point. As the geologist goes beyond that point he leans more and more on conjecture. It is very desirable, for his own sake as well as for that of the subject, that the actual data on which he proceeds should be definitely stated. His readers ought to know exactly where ascertained fact ends and restoration begins. Yet he may be so convinced of the truth of his restoration that, until challenged to set down in definite form the amount of evidence actually at his command, he may honestly have come to regard some of his deductions as well-established truths. He cannot, however, be too careful to draw a clear and sharp line between what he knows and what he infers, when it is his object to write geological history.

One of the most attractive branches of this history is that which deals with the gradual growth of a country or continent. Many interesting and important memoirs on this subject have appeared, more especially in England, where it has long been a favourite study. Sketch-maps have been published indicating in a somewhat vague way what the authors believe to have been the probable distribution of sea and land at former geological periods. Among those who by their original researches have contributed materials towards the restoration of ancient geographical conditions in Britain, Prof. Hull, the Director of the Irish Geological Survey, deserves honourable mention. His papers upon the changes that occurred during Carboniferous, Permian, and Triassic times, and upon the south-eastward attenuation of the Jurassic series in this country are well known to geologists. He has now, however, attempted a much more ambitious task than any one has yet ventured upon in this department of science. He has published a series of maps representing what he conceives to have been the successive geographical phases through which the region of the British Islands has passed from the earliest geological times. Without discussing the question whether the information at the disposal of geologists is yet sufficiently ample and precise to warrant an attempt of this kind, one may at least demand that every care should have been taken to show precisely what is actually known fact and what is inference. But Mr. Hull gives us scanty guidance in this respect. There is not one of his restorations that does not prompt the question on what grounds its details have been put together. The position of former areas of sea is usually sufficiently definable, but it is by no means so easy to say what was land, and still more difficult to assign even the most conjectural outlines to the shores. The author doubtless thinks his geographical boundaries vague enough; we are inclined to regard them as a good deal more definite than the actual evidence in many cases warrants. To take as an illustration his map of Britain during the Upper Silurian and what he terms the "Devono-Silurian" periods; we should like to know on what grounds he makes Wales, the Lake Country, the north-west of Ireland, and much of the Highlands of Scotland elevated land at that time. The evidence, so far as we are aware, is rather in favour of these areas having been under the Upper Silurian sea; at least we know of no proof that they formed high lands, even after the plication and metamorphism he refers to. Nor is there any information as to why the author marks the area from the mouth of the Humber to the middle of Norfolk as part of his continental land. He mixes up in a curiously unintelligible way his "Devono-Silurian" and Lower and Middle Devonian formations, some of the estuaries or lacustrine areas being placed with the older group of strata, others with the younger, in accordance with certain theoretical ideas which he has already published.

According to Prof. Hull's maps, most of the high grounds of Britain have been elevated dry land since the Lower Silurian period. No one, however, who has seriously studied how the land is continuously denuded, can believe this representation to be even approximately true. Our mountains must have been many times, and probably for long intervals, under water. Even if no large amount of sedimentary material were laid down upon them, their submergence would at least protect them from the degradation which would otherwise have worn them down. How does Prof. Hull know that Ireland, which was almost if not entirely under water during the Carboniferous period, did not remain more or less in the same condition through several succeeding ages? The presence of Permian and Triassic deposits in the north-east of the island shows that considerable denudation of the Carboniferous rocks had taken place there before these red strata were laid down. But surely it is rather a large inference from these slender data that all the rest of the country was land, with high grounds where we see them still. How can he tell that Ireland was not entirely submerged beneath the Jurassic sea? Had it not been

for the protecting sheets of basalt in Antrim, probably no fragment of Lias or Oolite would now have been left in the island. Prof. Hull submerges his country a little more in the Cretaceous period, but still keeps the high grounds as islands. Can he produce any evidence that they were so? Has he sounded the Cretaceous Ocean about which he is so precise? The denudation of Ireland has been unquestionably enormous, but had the country been above water as long as the Director of its Geological Survey imagines, we fear that every geological formation would have been worn off its surface down to the very platform of its fundamental or Laurentian gneiss. In fact the continued survival of the country above water could only have been maintained by repeated uplifts that in some measure at least compensated for its superficial degradation.

The chapters accompanying the maps furnish the reader with some of the information he requires to be able to estimate the extent of the data on which the restorations have been constructed. But they do not give him nearly enough of it. Some of their statements moreover will provoke criticism not less than the maps themselves. The author asserts, for instance, as if it were an established fact, that what he regards as the "essentially oceanic" conditions under which the Chalk was formed prevail from Ireland to the shores of the Caspian, and from Belgium to North Africa. We can hardly suppose him to be ignorant of the fact that the Chalk is but a local development of calcareous matter confined to the western part of the European area. Yet the author not only spreads the Chalk across most of Europe and into Africa and Asia, but proceeds to infer from this asserted extension that "according to all the laws of terrestrial mechanics" the site of much of the North Atlantic must have been then dry land. In other words, he first infers a wide deep ocean, and then creates a continent to keep it company.

One of the chapters, with the sounding title of "The Genesis of the North Atlantic Ocean," will be read with amazement by those who have watched the progress of recent research on this question. The author begins it by the following oracular announcement: "I date the genesis of the North Atlantic Ocean, properly so called, from the close of the Carboniferous period; and, consequently, from the same period, that of the British Isles and Western Europe." One is disposed at once to ask what may be his "exquisite reason" for this extraordinary statement, and he frankly volunteers it. It appears to be somewhat as follows:—The Carboniferous rocks of Western Europe were much disturbed at the close of the Carboniferous period, being thrown into east-and-west ridges. Similar movements took place over the eastern States of North America, the direction of the ridges being there more nearly north and south. It may be concluded, therefore, that the formation of the basin of the Atlantic Ocean formed part of these terrestrial movements!

In his Preface the author tells us how he had long entertained the idea of preparing such a series of maps as he has now published, and how he was deterred by the cost of publication. At last, in what we venture to think was an evil hour for his reputation, the Royal Dublin Society generously agreed to bear the expense. The maps were therefore prepared and published in the Society's *Transactions*, and a fresh impression has been printed off from the plates for the volume just issued. Fortune would have been kinder to one whose long services entitled him to gentle treatment at her hands had she induced him still to keep his restorations in the privacy of his own portfolio, at least for some years to come, or, if they must be published, had she insisted on greater accuracy in the statement of what is known and greater precision in the expression of what is conjectured.

OUR BOOK SHELF

Die Verwandlungen der Tiere. Von Dr. Otto Taschenberg, Privat-dozent in Halle. Pp. 268, with 88 Illustrations. Small 8vo. (Leipzig: G. Freytag, 1882.)

THIS forms the seventh volume of the series known as "Das Wissen der Gegenwart," the object of which is to give, in an attractive and popular form an outline of the "science of the day." Metamorphosis and development are always interesting subjects, and we are of opinion that Dr. Taschenberg has contrived to place them before his readers in a specially clear manner by choosing a few types in each class of the animal kingdom upon which to dilate, leaving the blanks to be filled in by more advanced students than those for whose instruction this elementary treatise is intended. The author goes in this manner through the entire animal kingdom, and so far as we can see he is well posted up in most of the latest discoveries and theories bearing upon his subject; we miss, however, any allusion to the disputed position of *Limulus*, although the metamorphoses of that remarkable animal are not entirely overlooked. A work such as this is naturally to a large extent a compilation, and in all such works the good or bad influence exercised depends upon the acumen of the author in his choice of subjects and authorities. In the present instance our author seems usually to have consulted the best and most modern authorities. The numerous illustrations are mostly very good; some of them are superlatively so. In these, as in the text, various works have been laid under contribution; and probably to no work is the author under greater obligation than the text-book on embryology by the lamented F. M. Balfour, but due acknowledgment is always made.

The concluding chapter is devoted to a sketch of the "evolution of species," in which, in a few pages, the author has contrived to give succinct historical information, winding up with a definition of "protoplasm," in connection with which a German translation from well-known English lines is given, and perhaps the definition was so modelled as to fit the lines. We reproduce them, just to show what latitude may be allowable in translation:—

"Der grosse Cäsar tot und Lehm geworden
Verstopft ein Loch wohl vor dem rauhen Norden.
O dass d e Erde, der die Welt gebebt,
Vor Wind und Wetter eine Wand verklebt."

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*

[*The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to insure the appearance even of communications containing interesting and novel facts.*]

Natural Selection and Natural Theology

I AM very glad to find from Prof. Asa Gray's last communication (NATURE, vol. xxviii. p. 78) that the result of our "amicable discussion" has been that of coming to an agreement on all

points save one, which, as he truly observes, is "seemingly capable of settlement by scientific inquiry." This point simply is as to whether variation in plants and animals is promiscuous (not "lawless") or is restricted to beneficial lines.

Now with reference to this point, I observed in my first letter (NATURE, vol. xxvii. p. 362) that if variation is promiscuous it is only the favourable variations that are able to survive, and hence the sole ground of entertaining natural selection as an agency in the process of evolution; but that, on the other hand, if it could be shown that variations always take place exclusively in the directions required for a development of the adaptations, so as to leave no room for the operation of natural selection, then the evidence of design as deduced from the theory of evolution would become comparable with that evidence as deduced from the theory of special creation. But I also pointed out that "the burden of proof lies with the natural theologian to show that there *has* been some such intelligent guidance of the variations, not with the evolutionist to show cause why there *may not* have been such guidance." And now I understand Prof. Gray accepts this as a correct statement of the case, observing in his last letter that, if variation is promiscuous, "then no doubt the theory of natural selection may be 'the substitute of the theory of special design,' so as to efface that evidence of underlying intelligence which innumerable and otherwise inexplicable adaptations of means to ends in nature was thought to furnish. If it is not so, then the substitute utterly fails."

It is most satisfactory to me that the issue has thus been clearly reduced to a simple matter of scientific observation, and I may add that I am much interested to find that a naturalist of such high standing as Prof. Gray still holds to the view that, "so far as observation extends, it does not warrant the supposition of omnifarious and aimless variation." Of course, if I had not believed in "aimless variation" as of universal occurrence in organic nature, I should never have supposed that the theory of evolution by natural selection could in any way touch the theory of special design; but finding that my fundamental belief in this matter is still open to question by so esteemed an authority as Prof. Gray, and observing that we are here upon the ground of a purely scientific question, I should like to say a few words in justification of this belief.

No one has attended to the subject of variation with a tenth part of the care that was bestowed upon it by Mr. Darwin, and no one has been gifted with a better judgment in matters of this kind. I shall therefore restrict myself to giving a brief outline of his matured opinion upon the subject.

Everywhere he speaks of variation as promiscuous or aimless, but never as "lawless," and only under a carefully guarded meaning as accidental. That is to say, he has no doubt that every variation is due to causes, though not of a teleological kind. Of these causes he regards changes of environment as highly important; but nevertheless he is inclined to lay less weight on these "than on a tendency to vary due to causes of which we are quite ignorant."[1] But with reference to variations not taking place exclusively in beneficial lines he says: "As man has domesticated so many animals and plants belonging to widely different classes, and as he certainly did not choose with prophetic instinct those species which would vary most, we may infer that all natural species, if exposed to analogous conditions, would, on an average, vary to the same degree. . . . We have abundant evidence of the constant occurrence under nature of slight individual differences of the most diversified kinds; and we are thus led to conclude that species have generally originated by the natural selection of extremely slight differences; . . . although each modification must have its own exciting cause, and though each is subjected to law, yet we can so rarely trace the precise relation between cause and effect, that we are tempted to speak of variations as if they arose spontaneously. We may even call them accidental, but this must be only in the sense in which we say that a fragment of rock dropped from a height owes its shape to accident. . . . If an architect were to rear a noble and commodious edifice without the use of cut stone, by selecting from the fragments at the base of a precipice wedge-formed stones for his arches, elongated stones for his lintels, and flat stones for his roof, we should admire his skill and regard him as the paramount power. Now the fragments of stone, though indispensable to the architect, bear to the edifice the same relation which the fluctuating variations of organic beings bear to the varied and admirable structures ultimately acquired by their modified descendants. . . . The shape of the fragments at the base of our precipice may be called accidental, but this is not strictly correct; for the shape of each depends on a long sequence of events, all obeying natural laws; . . . but in regard to the use to which the fragments may be put, their shape may be strictly said to be accidental. . . . Can it be reasonably maintained that the Creator intentionally ordered, if we use the word in any ordinary sense, that certain fragments of rock should assume certain shapes, so that the builder might erect his edifice? If the various laws which have determined the shape of each fragment were not predetermined for the builder's sake, can it be maintained with any greater probability that He specially ordained for the sake of the breeder each of the innumerable variations in our domestic animals and plants;—many of these variations being of no service to man, and not beneficial, far more often injurious, to the creatures themselves? Did He ordain that the crop and tail-feathers of the pigeon should vary in order that the fancier might make his grotesque pouter and fantail breeds? Did He cause the frame and mental qualities of the dog to vary in order that a breed might be formed of indomitable ferocity, with jaws fitted to pin down the bull for man's brutal sport? But if we give up the principle in one case,—if we do not admit that the variations of the primeval dog were intentionally guided in order that the greyhound, for instance, that perfect image of symmetry and vigour, might be formed,—no shadow of reason can be assigned for the belief that variations, alike in nature and the result of the same general laws, which have been the groundwork through natural selection of the formation of the most perfectly adapted animals in the world, man included, were intentionally and specially designed. However much we may wish it, we can hardly follow Prof. Asa Gray in his belief 'that variation has been led along certain beneficial lines,' like a stream 'along definite and useful lines of irrigation.'"[1]

I could give a number of other quotations to the same general effect from the writings of Mr. Darwin, but I think these are enough to show, as I have said, that if there is any evidence of variations being determined in special and beneficial lines, it now lies with the teleologist to adduce such evidence. If this could be done it would be a matter of immense importance, both from a scientific and a speculative point of view, seeing that on the scientific side it would be subversive of the whole theory of natural selection, and on the speculative side would therefore leave us where we were before the publication of the "Origin of Species." But at present the whole weight of such scientific evidence as we have appears to me unquestionably opposed to Prof. Gray's statement that, "so far as observation extends, it does not warrant the supposition of omnifarious and aimless variation."

Carson Footprints

IN NATURE (vol. xxvii. p. 578) which I have just seen, the Duke of Argyll calls your attention to the so-called human footprints uncovered in the prison yard at Carson, Nevada. I have carefully examined these tracks, and read a paper on the subject before the California Academy of Science, August 27, 1882. Unfortunately the *Proceedings* of the Academy have not yet been published, though copies of the several papers on this subject have been printed and privately distributed. Perhaps a brief account of these tracks will be interesting to your readers.

The nearly horizontal strata in which they occur consist of beds of sandstone with thin layers of fine shale. The track layer, which is one of these latter, has been uncovered over an area of nearly two acres, and forms the floor of the prison yard, while the stone removed has been used to build the prison. In the course of the excavation a number of fossils have been found, among which the most important are the jaws and teeth of an elephant, probably *E. Americanus*, and two species of horse, *Equus Pacificus* and *occidentalis*; some freshwater shells, all of recent species, have also been found. The age of the deposit seems to be that of the "Equus beds" of American geologists, which by some are put in the uppermost Pliocene, and by others in the lowest Quaternary. It is probably a transition between the two.

The whole surface of the shale exposed in the prison yard is literally covered with tracks of many kinds, but the mud was so soft when the tracks were made that the nature of many of them can only be guessed. Some were probably those of a horse; some probably of a wolf; some certainly of a deer;

many were those of long-legged wading birds. But the most interesting are those of the Mammoth and the problematical so-called human tracks. About the Mammoth tracks there can be no doubt. Some of these were uncovered by blasting in my presence; round basin-shaped impressions, 5 inches deep and 22 inches across, and occurring in regular alternating series, the hind-foot tracking almost perfectly with the fore-foot. The nature of the so-called human tracks, however, is far more doubtful. These occur in several regular alternating series of 15–20. In size they are 18–20 inches long, and 8 inches wide. In shape they are many of them far more curved than the human track, especially in soft mud. The stride is 2½ to 3 feet, and even more. The outward turn of the track is in many cases greater than in human tracks, especially in soft mud. But the most remarkable thing about them on the human theory is the straddle, *i.e.* the distance between the right and left series. This I found to be 18 and even 19 inches, which was fully as great as that of the mammoth tracks. This is probably the greatest objection to the human theory. On the other hand, the great objection to the quadrupedal theory is the apparent singleness of the tracks, and the absence of claw-marks. But it must be remembered that the tracks are deep, and the outlines somewhat obscure, and also that the mammoth tracks, on account of tracking of hind with fore-foot, are in most cases, though not always, single.

After careful examination for several days, the conclusion I came to was that the tracks were probably made by a large plantigrade quadruped, most likely a gigantic ground-sloth, such as the Mylodon, which is found in the Quaternary, or the Morothenium, which is found in the upper Pliocene of Nevada. The apparent singleness, the singular shape, and the large outward turn of the tracks I attribute to the imperfect tracking of hind and fore-foot on the same side, while the absence of claw-marks was the result of the clogging of the feet with mud.

This view seems to me most probable,[1] but many who have seen the tracks think them human, and I freely admit that there is abundant room for honest difference of opinion. On any theory the tracks are well worthy of scientific attention.

Berkeley, California, May 12 JOSEPH LE CONTE

[1] Views similar to my own have recently been expressed by Prof. Marsh and by G. K. Gilbert.

Cloudiness of Aquarium

CAN you tell me the reason why the water in my fresh water aquarium will not remain clear, but becomes cloudy throughout in a few days after filling.

The aquarium in question holds about twelve gallons of water. It stands in a window facing north. I have in the water two or three water-plants, among them a water-aloe. At the bottom are small gravel stones, which have been thoroughly washed before using. Floating on the surface for the benefit of a few newts is a piece of virgin cork, on which is placed some carpet moss. I had a dozen minnows and four newts to begin with, but nine of the minnows and two of the newts have died, manifestly from the fouling of the water.

The framework of the aquarium is iron, with a slate floor. The glass sides are fixed with red lead. There is a copper tube for overflow purposes, which was inserted when a fountain was used in the centre. This has now been removed and the water is stagnant.

It is now some years since I have kept an aquarium, and I cannot divine the reason for the above-mentioned cloudiness of the water. I shall be much obliged if you or some of your correspondents will help me. X.

May 9

So far as I can judge from "X's" description, the cloudiness of the water in his aquarium is due to the abnormal development of some unicellular algal (Palmellaceæ) or to the prolific spore-production within it of one of the filamentous forms (Confervaceæ). This may be obviated by screening the back of the tank from the access of light. Possibly "X" may find on examination that the cistern whence he obtains his supply has been left uncovered, and that the intruding algal has established itself and entered upon the reproductive process in that position. In that case he should either isolate the water he requires in a dark place for a week or so, when the spores will die, or obtain his supply from a purer source. An investigation with a high power of the microscope of the turbid water complained of will speedily determine whether the explanation here suggested is the correct one. By way of illustration, I may mention that the water of the ornamental pond in the centre of the Horticultural Gardens, supplied clear and bright shortly before the opening of the Fisheries Exhibition, had assumed within a few days and still retains the colour and consistency of green-pea soup through the rapid development, under the action of light, of a unicellular cryptogam in the manner above described. W. SAVILLE KENT

Singing, Speaking, and Stammering

REFERRING to the letters in NATURE (vol. xxvii. p. 580) on my classification of vowel sounds, allow me to explain:—

The classification given in the "Principles of Elocution" (4th ed., 1878) was retained from the earlier editions of that work, because of the difficulty, or impossibility, of exhibiting the complete vowel system of visible speech without V.S. symbols. For the purposes of the book on Elocution, the latter were not required; but a *note* (on p. 36) immediately preceding the "General Vowel Scheme" explains the basis of the complete classification developed in visible speech.

As you have given an abstract of my classification, quoted by Dr. Stone from "Principles of Elocution," I shall be glad if you will show your readers the following abstract of the visible speech classification:—

Classification of Vowels in Visible Speech

Nine Lingual positions yield 9 Primary vowels ... ...
Each Primary vowel yields a "Wide" variety by faucal expansion = 9 Wide vowels ... ... } = 18 Lingual vowels.
Each Lingual vowel yields a "Round" variety by labial contraction ... ... } = 18 Labio-lingual vowels.
} = 36 Normal vowels.
Each Normal vowel yields a possible variety by *higher*, *lower*, *broader*, or *narrower* formation = 36 + 144 = a total of 180 vowels.

The mutual relations of the different sounds may be exhibited in this way:—

LINGUAL.

	Primary.			Wide.		
	Back.	Mixed.	Front.	Back.	Mixed.	Front.
High	7	4	1	7	4	1
Mid	8	5	2	8	5	2
Low	9	6	3	9	6	3

LABIO-LINGUAL.

	Primary.			Wide.		
	Back.	Mixed.	Front.	Back.	Mixed.	Front.
High	7	4	1	7	4	1
Mid	8	5	2	8	5	2
Low	9	6	3	9	6	3

In this arrangement, each No. 1, No. 2, No. 3, &c., in the four sets is formed from one and the same lingual position. These relations are plainly exhibited in the symbols of visible speech. They cannot be shown by ordinary letters, but the use of *numbers*, as above, may make the arrangement clear to those who are not acquainted with visible speech.

Washington, D.C., May 12 ALEX. MELVILLE BELL

On the Cold in March, and Absence of Sunspots

I WAS travelling when Dr. Woeikof's letter appeared in NATURE (vol. xxviii. p. 53), and could not sooner reply to his criticisms on my communication (vol. xxvii. p. 551), "Unprecedented Cold in the Riviera—Absence of Sunspots." Let me first remark that I do not go so far as to "ascribe (as Dr. Woeikof says that I do) the great cold of March, 1883, at the

Riviera, to the absence of sunspots." My observations prove only the *coincidence* of a sudden and unprecedented visitation of cold, with an absence of sunspots (the more remarkable as occurring during a *maximum* sunspot period); and the further *coincidence* of a progressive rise in temperature with the return of the sunspots; but I add, "These observations are too few and too imperfect to warrant any decided conclusions; but they add to those already made in evidence of the connection between the absence of sunspots and the diminution of terrestrial heat; and I trust they may be followed by further and more exact investigations, to determine the influence of our great luminary on the weather and climate of the world."

It does not appear to me that Dr. Woeikof has succeeded in establishing a parallel between Cannes and Suchum-Kale on the Black Sea; which, however sheltered locally, must, far more than Cannes, be liable to chilling influences in the cold winds from the lofty mountains and vast elevated steppes to the north, extending even to the Arctic regions. Therefore the fall of 31° below average in March, 1874, might not be extraordinary, even in a *year* with a considerable number of sunspots. It is not stated that the spots continued in this particular month.

The case of Cannes may be thus stated: With a climate usually so mild in winter that frost and snow are of rare occurrence; and this winter, with slight frost only three times before February, and none at all in that month, the average minimum being 44°,—on March 7 minimum fell to 36°, with a heavy fall of snow; and on the 8th, 10th, 11th, and 12th, the minimum fell further to 27°·7, 27°, 24°·1, 25°·7. The sunspots, which had been observed by my friend, Mr. Campbell, of Islay, to be large and active until February 26, suddenly disappeared, and on February 28 and March 3 I found no spots; on the 10th and 11th only one or two small spots. On the 12th they began to appear in numbers, with a large oval facula. From that day they continued to increase, and the temperature gradually rose to the ordinary average.

I will not occupy space with further arguments, but I will merely state some more facts with regard to the extraordinary intensity and universality of this invasion of cold, and my further observations of the sunspots. At my villa at Cannes, which is favourably placed in position and shelter, the register did not fall so low as in other parts. At Dr. Frank's villa, Grand Bois, more open to the north (thermometer in louvred box, a metre above ground), the minima were: March 7, 27°; 9, 25°·2; 10, 21°; 11, 21°; 12, 20°; 13, 25°. At Villa Beaulieu, more sheltered (therm. also in louvred box), minima were: March 7, 29°; 9, 27°; 10, 25°; 11, 26°; 12, 28°. Dr. de Valcourt's minima are somewhat higher; but he adds this note: "La période de froid du 7 au 14 Mars, 1883, a été très remarquable; elle est unique, depuis que les observations regulières ont été recueillis à Cannes." Where instrumental records are wanting, we refer to the report of the "oldest inhabitants," and learn that there has not been a cold so severe or destructive to oranges and olives since the year 1820.

Extraordinary and intense as was this invasion of cold, it might have been supposed due to local or regional causes only, had it been confined to Cannes and its neighbourhood. In my former paper I stated that I was not informed how far the cold had extended to other countries and latitudes. We still need further exact information on this point, but what has already reached us goes far to prove that the cold was universal, and not limited to a region. In England, Mr. Thomas Plant writes to the *Times* from Moseley, Birmingham:—"After one of the mildest winters registered in the Midland Counties, the month of March, which is generally expected to be the beginning of spring, has been colder this year than any corresponding month for 38 years." "When we consider the power of the sun in March, as compared with December, January, and February, then we can realise some idea of the prolonged and most abnormal cold of the month now ended." By private information I learn that at the same time, in Stockholm, Centigrade's thermometer fell 13°, and at St. Petersburg 18°, below freezing. Unusually intense cold in March is also reported from Canada. In the south we hear of snow and frost in South Italy, Sicily, Algeria, Egypt, and even Nubia. Later still there have been reports of snow on the mountains of Madeira and California, where it had never been seen before.

Since March 19, the date of my former letter, I have been able to make sketches of the sun's position on 49 days.[1] Of these observations the following summary may suffice. In number the spots varied from 3 to 18; the larger showing, more or less, holes or clefts of central umbra, with fringe of penumbra. Faculæ, or clouds of whiteness, were often seen around the larger spots. The spots varied in number and form from day to day; and although the same large spots and even groups could be traced for several successive days, they never retained the same aspect during the whole period of the sun's semi-rotation. On April 17 the spots were at their maximum; in number 18, in three groups. During this period, from March 19 to April 19—thirty-one days—the mean minimum temperature was 46°·2, mean maximum 57°·9.

From April 20 to May 7 there was considerable diminution of the spots; numbers not exceeding 8; and on May 7 there was only one large spot, with surrounding facula. The mean temperature of these seventeen days was—minimum 49°·8, maximum 60.

From May 8 to 16 spots were few, from 2 to 8; but two of them were very large, with umbra and penumbra and sometimes adjoining faculæ. The mean temperature of these nine days was—minimum 52°·7, maximum 63°·8.

Here my observations terminate, as I left Cannes on the 16th, and have no means of observing in London, even if the atmosphere permitted. But I conclude by strongly commending the attentive study of the sun not only to astronomers and physicists, but also to practical meteorologists, as an interesting and not difficult addition to their work of observation, and one likely to supply information concerning the most important factor in the problems of weather and climate. C. J. B. WILLIAMS

47, Upper Brook Street, May 25

[1] I use only a modest achromatic of 32 inches focus, and 2¼ inches aperture, which, projecting the solar image on a white card, exhibits the spots with umbra and penumbra, and the faculæ, sufficiently for this purpose. Of course a more powerful instrument would show a great deal more, both in number and in construction of the spots. For instance, on April 17, when I made out 18 spots, Mr. Campbell's solar image exhibited 104, with marvellous variety in the larger spots, and in the dome-like expansion of the adjoining faculæ. But these details, so deeply interesting in heliography, are not wanted for meteorological purposes.

The Soaring of Birds

MY thanks are due to Mr. R. Courtenay for the notice he has taken (NATURE, vol. xxviii. p. 28) of my letter on the Soaring of Birds (vol. xxvii. p. 592). It is a great satisfaction to me to find my general conclusion supported by his observations. As to the possibility of a soaring bird utilising a downward current of air, I stand corrected. There is no difficulty in agreeing with Mr. Courtenay that the bird, finding itself in a downward current "will descend swiftly so as to acquire the necessary impetus for a rapid escape;"—that is to say, it will seek to make the best of a bad bargain. But it is not so easy to see that the bird, in a current approaching the perpendicular, will "acquire an impetus much more than compensating for the slight loss of elevation;"—that is, will actually make a profit out of a seemingly adverse condition.

This paradox, however, becomes more acceptable by the aid of an illustration:—A marble held lightly just within the rim of a hemispherical bowl, if let drop, will barely reach the opposite rim, but, if struck sharply downward, will run up the opposite side and leap up above the opposite rim. In like manner a bird, struck by a downward current as by a hammer-stroke, may speedily acquire a downward velocity greater than that due (under gravity) to the height through which it has descended; and may therefore rise, if it can escape from the downward current into a horizontal (or *a fortiori* into an upward) current, to a greater height than if it had fallen from the same starting-point through still or horizontally-moving air.

I am very much obliged to Mr. Courtenay for pointing out this interesting result. It gives completeness to the theorem, which now stands thus: that any alternations in the strength or direction of air-currents can be so utilised by birds as to enable them to soar. HUBERT AIRY

Woodbridge, May 25

The Zodiacal Light

THE phenomenon to which your correspondents allude, under the head of zodiacal light, was seen by me in the month of April, 1852. At the time I wrote a letter to the *Times*, in which I suggested it might be caused by the reflection of the sunlight at the surface of two masses of air of different densities, however irregular the bounding surface might be, in the same manner as the line of light seen reflected between the observer

and the sun across the sea. One of your correspondents has suggested a more probable origin, viz. particles of ice in the air. From other correspondents it seems that the sun column is not always vertical, which might be the result of the general flame of the reflecting surface not being parallel with the earth's surface.

In the June number of the *Philosophical Magazine* there was a notice of a sun column as seen at Orkney by the Rev. C. Clouston, who at that period made meteorological observations for that publication. He says that in the month of April of that year the drought was unprecedented, the atmospheric pressure great, and the temperature high. I believe two of these characteristics belonged to the recent month of April if not the third, the high temperature. He says it was seen six times, and once or twice before he noted the date, and also before sunrise.

Saltburn, May 21 E. R. TURNER

Sheet Lightning

MAY not this be an auroral phenomenon, at times, at least, and hence the differences of opinion as to its nature? Reading Wilkes's "Narrative of the U.S. Expedition," I find the following:—"On the 7th February (1840) the weather had become less boisterous, and having reached latitude 49° S., longitude 155°·23 E., the aurora Australis again appeared. It was first seen in the north, and gradually spread its coruscations over the whole heavens; the rays and beams of light radiating from nearly all points of the horizon to the zenith, when their distinctive outlines were lost in a bright glow of light, which was *encircled by successive flashes, resembling those of heat lightning on a summer's night.* These formed a luminous arc in the southern sky, about 20° in altitude, from the upper part of which rays were continually flashing towards the zenith. Light showers of rain finally shut it out from view." FRED. PRATT

Clapton Park, May 25

Pocky Clouds

FOR twenty years I was constantly observing the forms and appearances of the clouds, as clues to the weather and its changes. I observed this form on a very great number of occasions, and from experience always came to the conclusion, "no rain today," and I can only remember two occasions on which the conclusion was not justified. I saw it again a few days ago, with the same result of good weather.

I always termed it the "bubble" cloud till I saw Dr. Clouston's work. It seems to me to be a body of vapour the upper surface of which is being acted upon by an upper current of very dry and rarefied air, causing a great and rapid evaporation, and thence a gradual and unequal cooling and shrinkage of the under surface in the detached globules from which it takes its name. I have seen a very simple illustration while passing through the laundry, and observing a neglected trough of soap-suds cooling down and nucleating in the exact form presented by the pocky cloud, and with the same gradations of tint.

This kind of cloud is generally observable at periods most probable for storms and electric condensations, the which, acting at a distance, would influence outlying areas of upper atmosphere and cause this form of cloud condensation in the way explained. In my observations I have generally found the cloud revert to uniform sheet stratus rather than to disappear in cloudlets in the upper air. FRED. PRATT

Clapton Park, May 25

Clerk Maxwell's "Devil on Two Sticks"

IN the very interesting life of Clerk Maxwell which has lately appeared there are frequent references to a philosophical toy, from which he seemed to derive endless amusement. He calls it the "devil on two sticks." Can you give your readers any account of it? The editors take it for granted that the apparatus is well known, but I cannot find any one here who can tell me what it is. DENNY LANE

72, South Mall, Cork

The Centres of a Triangle

CONTINUING my suggestion in your number of May 3 (p. 7), I propose not only to call the circle circumscribing a triangle the *circumcircle*, but also to call its centre the *circumcentre*, and in the same way to speak of the *incentre*, the three *excentres* (namely, the *a*-excentre, the *b*-excentre, and the *c*-excentre), and the *midcentre*.

The line joining the circumcentre to the orthocentre, on which the masscentre and the midcentre lie, may be appropriately called the *central line* of the triangle.

Similar abbreviations would apply to the radii of these circles; they might be spoken of as the *circumradius*, the *inradius*, the a-*exradius*, the b-*exradius*, the c *exradius*, and the *midradius*.

May 25 W. H. H. H.

THE ROYAL GEOGRAPHICAL SOCIETY

THE annual meeting of the Royal Geographical Society on Monday was of rather more than usual scientific interest. Sir Joseph Hooker was presented with the Royal Medal which the Society has awarded him, Mr. Colborne Baber being the recipient of the Patron's Medal; while among the speakers at the dinner, besides Sir Joseph Hooker, were Mr. Spottiswoode and Prof. Huxley. From the address of the President, Lord Aberdare, it is evident that geographical research, and especially exploration, has been as active as ever during the past year, yet, as the speakers we have named pointed out, the discovery of new countries must have a limit, and in time must come to an end. Still there will be plenty of work for geographers to do in the wider acceptation of the term geography, implied in the presentation of the Royal Medal to so distinguished a botanist as Sir Joseph Hooker. In the words of Mr. Spottiswoode, and as we have frequently pointed out in these pages, geography in its modern acceptation includes "an accurate delineation of the earth's surface, and an exact account of its inhabitants and of their habits, of the animal and vegetable life, and its distribution over the face of the globe." In this direction the Society has a long and brilliant career before it But as Prof. Huxley humorously pointed out in replying for the "other societies," these societies "were all growing a little dull. He did not say this in the way of reproach. The progress made in research and accuracy in methods of procedure involved that consequence. So long as there were large regions of knowledge which the methods of modern science had not penetrated, so long was it possible to go to meetings of societies, and to hold brilliant discussions. Looking at the means which now existed for the diffusion of information, he had been led to think that in many cases where the field of knowledge had been extensively explored the utility of societies was constantly diminishing, and that sooner or later it would be necessary to devise other means of effecting the results now attained by meetings of societies. But there was one thing which would not be reached at any period of time by any other organisation than that of societies, and that was the stimulus which was given by their meetings to investigators; and the reward they found for their toils and sacrifices in such a welcome as had been given that night to his long-tried friend Sir J. Hooker."

The prosperity of the society continues to be maintained. Mr. Clements Markham read the annual report, which showed that during the year the number of Fellows elected was 163, besides three honorary corresponding members, and the total number of Fellows on the list (exclusive of honorary members) was 3392. The total net income for the financial year ending December 31, 1882 (exclusive of balance in hand and 1005*l.* sale of Exchequer Bills) was 7937*l.*, of which 5652*l.* consisted of entrance fees and subscriptions. The net expenditure during the past year was 8779*l.*, including 1135*l.* spent on expeditions. The sale of 1000*l.* of Exchequer Bills was rendered necessary to meet the Society's contribution to the Eira Relief Expedition, but this sum had since been generously presented to the Society by Mr. Leigh Smith. The investments and assets of the Society on December 31, 1882, exclusive of the map collection and library, amounted to 39,831*l.*

THE TRUE ORBIT OF THE AURORAL METEOROID OF NOVEMBER 17, 1882

AFTER many fruitless efforts to conciliate the apparently widely diverging data, given by the numerous observations of this most interesting phenomenon; and after having been many times on the same point as Mr. H. D. Taylor (vol. xxvii. p. 434), who has given the first approximate calculations of this orbit, namely, "to give up the reconciling of such contradictory evidence," I have devoted my Easter holidays to new research on the true orbit. Besides the encouraging letters received from some of the English observers, I found still another motive in the observation of Mr. Julius Dupire at Laon (France, $\beta = 49° 34'$), who had the kindness to give me ample information, for which I offer him my sincere thanks, and in the communication of the following citation, kindly given me by Prof. Ch. Montigny, of Brussels, taken from the *Bulletin de l'Observatoire de Bruxelles*, November 18, 1882: "À 6h. 23m. un énorme rayon d'un blanc vif s'éléva à l'horizon E.N.E.; il traversa le ciel en passant le zénith et alla s'éteindre à l'horizon O.S.O." A similar phenomenon has been observed by Dr. F. Terby at Louvain. The great attraction of the Laon observation consisted in the fact that the meteor's apparent path was there seen at the north side of the zenith, this being in harmony with the Brussels zenith observation, and promising a good determination of the sought orbit.

In the first place I took the following apparent orbits from the numerous given observations. They can or must be taken as great circles, and must, in this case, fulfil the condition of intersecting one another in two opposite points of the sphere. In fact their intersections are contained within a small space and gave me an approximate position to one of these two points, $\alpha = 70° 30'$, $\delta = + 14° 30'$.

These five apparent orbits, the only ones given completely, are the following:—

No.	Place of observation.	Pages of NATURE, vol. xxvii.	Data of observation.	Deduced horizontal direction.	Local time of max. elevation.	Observer.
1	York, $\beta = 53° 58'$.	87, 140, 434	The centre was 6° or 7° below the moon's centre (given not directly after observation); 30° elevation in meridian (probably a mistake or a printer's error, being in contradiction with the other data).	E. 20° N.–W. 20° S. (nearly); deduced by the observer.	6h. 4 or 5m.	H. D. Taylor.
2	Clifton (Bristol), $\beta = 51° 28'$.	85	8° from Saturn, to the right, in a line inclined 45° to the horizon.	E. 20° N.–W. 20° S.	6h. 4m.	A. M. Worthington.
3	Old Windsor, $\beta = 51° 30'$.	87	First seen a little S. of Aldebaran; moves across the moon's disk.	E. 20° N.–W. 20° S.	6h. 6m.	John L. Dobson.
4	Utrecht, $\beta = 52° 5'$.	296	Aldebaran and two points in the equator at 110° and 290° R.A.	E. 20° N.–W. 20° S.	6h. 24m.	Prof. J. A. C. Oudemans.
5	Zonnemaire (near Zierickzee), $\beta = 51° 42'$.	296	Aldebaran and β Pegasi (α Pegasi on p. 296 was a printer's error).	E. 20° N.–W. 20° S.	6h. 21m.	P. Zeeman.

Tracing these five apparent orbits on a celestial globe they gave the intersection point above mentioned. It is clear that this point, joined with the eye of the observer, gives the direction of the true path. This point lying further, the globe being placed on the different latitudes and hours, not far from the point E. 20° N. of the eastern horizon (at Utrecht 7° above the horizon), it is evident that the lines of intersection, formed by the plane of the mean horizon with the planes of the apparent orbits must be nearly parallel to this direction. That these lines of intersection cannot be true parallels follows from the observations of the four students at Cooper's Hill (p. 97), from that of Mr. Joseph Clark at Street, communicated by Mr. J. E. Clark, at York; and from that of Mr. A. S. P. at Cambridge (p. 87), who saw the phenomenon disappear in the S.W., S.W. and S.S.W. Further the *Revue Mensuelle* of M. C. Flammarion (2me Année, p. 72), containing a short report of Mr. Dupire's observation, mentioned above, gives also an observation made at Ploërmel ($\beta = 47° 55'$, λ 2° 23′ W. Greenwich), where the phenomenon disappeared in the west.

Now I have drawn a stereographic map on a large scale, and brought the intersection of the vertical plane through Brussels, with the bearing E. 20° N. It is clear that the true orbit must lie in the vertical plane. Further I have constructed the angles formed by the planes of the apparent orbits with the respective horizons, correcting, if necessary, for the curvature of the earth, and after much trouble found the following path, being a straight line having the properties given in the table on p. 106, that enables us at the same time to compare the results of my construction with the data of the different observations given in order from E. to W.

I hope that the observers will be content with the degree of harmony between their observations and my results. I believe that a small change in the direction of the orbit's plane will give still more harmony between calculation and observation, but the orbit found satisfies the chief observed facts, and gives the greatest divergence, where the observations have the smallest sharpness. I believe I have proved by this research that there existed, with the aurora of November 17, 1882, cosmic dust, passing through the upper strata of our atmosphere with great velocity, and giving, according to the most interesting observation of Mr. Rand Capron (p. 84), "the usual green line" of the aurora spectrum. Thus nature itself has been so kind as to give an experiment that till now, and perhaps for ever, is beyond human

Places of observation.	Height of path in kilos.; meteoroid at max. alt. above horizon.	Max. altitude of the apparent path: Deduced from the found path.	Max. altitude of the apparent path: Deduced from observation.	Comparison of the position with regard to the moon: Constructed.	Comparison of the position with regard to the moon: Observed.	Horizontal bearings of the apparent path: Constructed.	Horizontal bearings of the apparent path: Observed.	Observers.	Remarks.
I. Utrecht.	159·5	54°	54°	—	—	E. 22° N.	E. 20° N.	Prof. J. A. C. Oudemans.	The inclination on the horizon, from observation 6° to 7°, from construction 7°.
II. Zonnemaire (near Zierickzee).	150·6	56	62	—	—	E. 22° N.	E. 20° N.	P. Zeeman.	The altitude 62° uncertain, according to the observer's letter.
III. Brussels.	149·1	90	90	—	—	E. 20° N.	E. 22° 30′ N.	(?)	From the *Bulletin* of the Observatory. The horizontal bearing was given E.N.E.
IV. Laon.	140·9	51½	60 to 65	—	—	W. 17° S.	W.	Jul. Dupire.	The maximum altitude seems to have been determined by estimation.
V. Ipswich.	135·1	—	—	The centre 1° above the moon's centre.	Exactly across the moon.	E. 21° N.	E. 10° N. (?)	Hub. Airy.	The eastern horizon cloudy, the width of the meteoroid 5°.
VI. York.	134·3	—	—	The centre 10° below the moon's centre when nearest.	The centre 6° to 7° below the moon's centre when nearest.	E. 37° N.	E. 20° N. (p. 434) given by the observer.	H. D. Taylor.	The angle below the moon's centre is given from memory (p. 140), and was difficult to estimate. I find the horizontal bearing of the apparent path, given by the observer, E. 25° N. The small inclination to horizon makes it very uncertain.
VII. Cambridge.	133·5	—	—	—	—	W. 51° S.	S.S.W., or W. 67° S.	A. S. P.	It disappeared below the horizon in the S.S.W. (p. 87).
VIII. Greenwich.	132·1	—	—	The centre 5° above the moon's centre.	A little above the moon (p. 83).	About E.N.E., W.S.W.	E.N.E., W.	W. H. M. Christie.	P. 83.
IX. Lincoln's Inn Fields (London).	132	—	—	Across the moon's disk.	Across the face of the moon.	—	—	Edw. Pollock.	P. 141.
X. Cooper's Hill (near Windsor).	130·6	—	—	Nearly above the moon, the centre about 2° above the moon's centre.	Just below the moon.	S. 58° W.	S. 45° W.	Messrs. Sykes, Wildeblood, Thornhill, and Wackrill.	P. 99. Communicated by Mr. Herb. McLeod. The meteoroid being seen from Windsor and from Lincoln's Inn Fields, to the north of Cooper's Hill *before* the moon, it could not *possibly* be *below* the moon, when seen from Cooper's Hill. There *must* be a mistake in the communication or in the observation. The being *before* the moon is naturally a *fact*, where a mistake is *impossible*.

power, for our means are not sufficient to throw projectiles with several thousand metres velocity; and it is very remarkable that this experiment comes at the same time as the interesting experiment of Prof. Lemström, showing that electric currents are able to give a development of light in our atmosphere, possessing the same number of undulations in a second as the auroral light. Now our meteoroid being a part of an aurora, it gives a stronger proof of the origin of that phenomenon than Prof. Lemström's experiment, the greatest attraction of which is that we are able to repeat it arbitrarily and with our own means. Further, I have always maintained that electricity, excited easily by friction, must be one of the causes of the auroral light ("Théorie Cosmique de l'Aurore Polaire," *Journal des Spectroscopistes Italiens*, 1878, vol. vii. chap. ii.), and it seems to me very plausible that cosmic matter, approaching the earth, induces electric currents through the air. Therefore I think that the results of Prof. Lemström are in full harmony with the idea of a cosmic origin of auroræ.

The orbit found does not reach the surface of the earth, being at its nearest approach still 123·9 kilometres (1 mile = 1609·3 metres; 1 German geogr. mile = 7420·4 metres) or 16·7 geogr miles from that surface. The length of the orbit from the Utrecht perpendicular line to the Utrecht horizon is 1,483,070 metres, and this line being run over in 60 seconds,[1] the mean relative velocity was 24,673 metres, 15·3 miles, or more than 3 German geogr. miles.

The dimensions of the "cosmic cloud" (length 40°, width 5°, as seen from Ipswich) are: length = 182,594, width = 21921 metres. By these dimensions, probably too great from irradiation, it must show at Utrecht an apparent length of 50°; but the extremities were tapered and therefore the length strongly influenced by the transparency of the air. It is therefore not strange that the apparent length at Utrecht was during some few seconds 90 degrees.

To conclude, I will remark that the proved existence of a cosmic cloud, preserving its pretty sharp sides during so long a path as that from Sweden to the Atlantic Ocean, notwithstanding its velocity of 247 kilometres, proves its particles to be nearly spherical. Otherwise these particles should necessarily have diverged sideways from the orbit and spread into space. In connection with the fact observed by Mr. P. Zeeman (p. 297), that auroral clouds gave interference-phenomena, when coming before the moon's disk, and these latter phenomena requiring (Dagnin, "Traité de Phys.," iv. p. 446) the presence of nearly equal particles of dusty matter, Mr. Zeeman's observation proves the same property in the particles of the auroral cloud. Being nearly equal, but not perfectly, the tangential atmospheric resistance must throw the smallest particles backward, and this explains the oblong shape of the cloud.

In presenting my results and reasonings to the readers of this journal, I hope that they will remember that this paper has been written in a shorter time than the author had wished. H. J. H. GRONEMAN

Groningen (Netherlands), April 7

THE AURORA BOREALIS[2]

II.

THE Aurora Borealis at Sodankylä.—Although the aurora borealis often appeared with considerable intensity, it did not boast many varieties. It began generally with a faint arc in the northern sky, which soon developed into a sharp arc, with streamers and a kind of luminous "drapery" spreading from east to west. The colour of this luminous drapery was not very changeable, so that the spectroscope only returned the usual yellow-green line. Generally it was of a yellow-whitish colour, with a slight shade of green.

There was, however, an observation made of far greater interest, viz. that the spectroscopic "reaction,"[1] *i.e.* $\lambda = 5569$, on several occasions was returned from every quarter of the horizontal plane, even from the zenith, *without any aurora being visible.* As this reaction was obtained while the ground was still bare, there can be no question of its being a reflection, but that this place was at the moment within the sphere of an auroral discharge, but of such a weak character that it did not appear in the form of aurora borealis. This observation was therefore precisely similar to the one made in 1871 in Lapland, described above.

These observations were chiefly made by my assistant, Herr Biese, who made another remarkable discovery. Nearly due south-east from the Observatory, he received on several occasions a spectral reaction from a narrow belt of the sky, *although no aurora was visible.* This observation, which was very difficult to effect, as the eye had to be kept entirely away from all light for fully five minutes before the reaction could be traced, I had myself several opportunities of corroborating. In this direction were situated some mountains 300 metres high, about 30 kilometres distant, and in my opinion the reaction was due to the above-described phosphorescent flames, which were seen around the mountain-tops in Lapland and Spitzbergen. All observations were of course made after *every trace* of daylight had disappeared.

The Phosphorescent Luminosity.—On several occasions the attention of travellers in the Arctic regions has been attracted to a peculiar soft light or "shine" during the night. But, as the change from day to night is very gradual in the Polar regions, as compared with that of southern climes, a certain amount of exertion of the mind is required in order to take cognisance and retain the features of this phenomenon. As, however, attention has been once drawn to the same, it will always be observed. Already in October I noticed it at Sodankylä, and directed the attention of my assistants to it. I give subjoined some extracts from my diary concerning this phenomenon:—

December 9, 1882.—The Polar night shows sometimes a peculiar phosphorescent "shine" or diffused luminosity, which possesses several phases, but the general character of which is a luminosity of a yellow-white colour, which renders the night as light as the moon with a thick hazy air. I take here the appearance and disappearance of the light on two nights when its intensity was greatest.

On December 6 I was on a journey between Orajärvi and Sodankylä. The phenomenon became then apparent at 7 o'clock p.m. When daylight had completely disappeared, there seemed to remain a faint light in which the outlines of objects around could only with difficulty be discerned. At 7.40 this increased, however, so rapidly that in a few moments every object around stood out clearly in a yellow-white hazy phosphorescent luminosity of quickly-shifting intensity. I had unfortunately no photometer by me by which I could determine the same. It lasted in this form until about 10 o'clock.

December 8, at 5 p.m., I walked from the Observatory to the church near it, in order to observe from its steeple some fire-signals from Oratunturi. On the way, I noticed that a yellow-white luminosity of shifting intensity filled the entire horizon, while twenty minutes after it had increased greatly in intensity, and was now strongest in the north, whence it gradually faded to the south, where it had least intensity. Near the horizon it was difficult to discern the stars. Higher up it was, however, easier, and from 60° to the zenith the sky was clear, of a mauve colour. It was exceedingly interesting to compare the light with the Milky Way. The yellow-white light

[1] This number is stated also by the sharp determination given by the Astronomer Royal, Prof Christie.

[2] Continued from p. 63.

[1] [By this term Prof. Lemström of course refers to the *characteristic line in the spectrum* of the aurora. The term might be justified by analogy with the "reactions" characteristic of the presence of the various chemical elements.—ED.

contrasted sharply with that of the latter, particularly where the Milky Way stood out of the same. In the yellow-white light it was difficult to make out the Milky Way. This phenomenon lasted far into the night. Later in the evening, between seven and nine, there appeared an aurora of great intensity, of which I shall speak below. This luminosity gave no reaction in the spectroscope at our disposal, but no doubt it would have been obtained had this been less absorbing. Thus, for instance, the larger Wrede's spectroscope (four prisms) did not give the reaction of the auroral phenomenon at Oratunturi, whereas the smaller, as stated above, really showed the line.

There is not the least reason for assuming that this luminosity is of any but an auroral nature, and the result of these observations is *that the whole of northern Lapland is during most winter nights illuminated by a phosphorescent luminosity*, whose intensity varies greatly according to period and place, *but which is undoubtedly of an auroral nature.*

On the same day, viz. December 8, the expedition was enabled to make the first measurement in the magnetic meridian of the elevation of the auroral arc. The wire, which was laid out north and south for the study of the terrestrial current, was used as a t lephone line, and the observations thus made by signals. Two theodolites with the necessary instruments were employed, viz. one at Sodankylä and the other about 4·5 kilometres distant to the north, near the mouth of Kälujoki. The observations at the observato y were made by Herr Biese, and at the northern end of the telephone line by Herr Petrelius. The auroral arc appeared in the north and shone with a quiet, subdued light, while a streamer now and then shot forth into the sky. Six measurements were made with the following result :—At the northern station the line of sight formed, with the under rim of the arc and the horizontal plane, an angle of 9°, and at the southern station one of 12°, *i.e.* an angle 3° larger at the southern than at the northern station ! Even assuming that both observers saw *the same* arc, the result is absurd, as however great the distance between the two might be, the difference of the angle would be very small indeed, and, if a difference at all, the angle of the *northern* station should have been the greatest. As, however, the reverse was the case, I have come to the conclusion *that the two observers did not see the same aurora.* A corroboration of this opinion is that on one occasion Herr Biese telephoned, "Turn the instrument to where the *red* column is," while at the northern station no such colour could be traced. This was proved still further during the return journey from Kultula to Sodankylä by the following circumstance. At Köngäs, 60 kilometres north of Sodankylä, on January 3, 1883, at 4 p.m., the whole horizon was flooded with a yellow-white luminosity of great intensity. At the same time an auroral arc formed in the south about 25° over the horizon, and a similar one was at the same moment observed at the same elevation in the north from Sodankylä. The departure from Köngäs took place just after 4 p.m., and during the journey this arc gradually disappeared, while the luminosity and the arc seen at Sodankylä were seen all through the evening. Here there was an opportunity of measuring the elevation of the auroral arc, but as I was convinced that the two phenomena were not the same, I did not attempt it.

It was clear that we were within an auroral discharge which extended considerably east and west, but the main strike of which was north and south. It is very probable that the electric current which caused this light some thousand metres above the surface of the earth also produced the above-described intense luminosity in a layer some 20 metres in depth, running parallel with the earth. It was this layer which was projected from both points into the sky in the shape of an arc. But it is clear that the auroral "drapery" did not penetrate far into the horizontal plane, but as it is generally produced in the centre of a weak discharge of great penetration its appearance from various places in the line north and south would be very variable according as the layer lends its light to the drapery.

The measurements and results described above exactly correspond with those of Mr. Fritz in Greenland (*Bulletin de la Commission polaire Internationale; Mittheil. der Internationalen Polarcommission*, Heft 3), where he obtained an auroral drapery of 650 feet, 1700 feet distant from the observer, and another one of 170 feet, 350 feet distant.

Without further discussing this question here I must state that I consider that *all* measurements of the height of the aurora, calculated on those with a long base north and south, are always erroneous, as the two observers *never* see the same aurora. And even those calculations which are based on the measurments of the height and length of an arc from *one* point, and the hypothesis that the arc extends around the magnetic pole, must be considered very unreliable, as no satisfactory answer can be given as to what results would have been obtained a little further north or south. This is also the case with auroræ with long bases east and west, as only on a shorter distance is it possible to say if it is the same phenomenon which is seen.

That the height of the aurora borealis is very variable I fully admit, but in my opinion it has been greatly overestimated.

Researches with the Terrestrial Current.—During my expedition to Lapland in 1871, we examined the terrestrial current in two places, viz. Kittilä, lat. 67° 40′, and Enare Vicarage, lat. 68° 55′, with wires 1½ kilometres long—east and west, north and south—of copper 0·4 mm. in diameter, and finishing in platina disks 10 cm. by 5 cm., buried in the earth at a depth of 0·7 to 0·9 metre. The deflexion was measured by a galvanometer with astatic needles with telescope and scale (Weber's magnetometer, of Edlund's improved construction). The remarkable result obtained here was that the galvanometer at Kittilä, with the current east and west, gave a deflexion equal to 60 to 100 parts of the meter scale, whereas the current at Enare only gave *a fraction of one part of the meter.* With the current north and south, the difference was not so great, although even here the deflexions were smaller at Enare. It was unfortunately impossible to ascertain if this remarkable phenomenon was due to *latitude* or *season*, the researches at Kittilä being made in October, and those at Enare in the latter half of November, while on the former occasion the ground was not frozen, which it was on the latter.

The Finnish expedition this year to Sodankylä has also examined the terrestrial current, viz. during certain periods of the phenomenon every five minutes, at other times once every hour, with a wire 5 kilometres long, terminating in small platina disks in the earth. During my visit to Kuttala—Decem er 22 to January 4—I also tested the terrestrial current, but with a wire only 1 kilometre in length, running east and west. Here, too, no deflexion was shown, while in Sodankylä the current was just as strong as ever. At Kuttala the galvanometer was certainly not so sensitive as at Sodankylä, still, the experiments of 1871 are even in this respect not without importance.

I have, therefore, from these researches drawn the inference that, while the condition of the ground is of some influence, *the terrestrial current ceases at a certain latitude.* In 1871 already I maintained that the terrestrial current was caused chiefly by the electricity which descends from the atmosphere in the belt around the Pole, in which the aurora borealis attains its maximum, and my recent researches at Sodankylä have greatly confirmed this theory.

I now intend to discuss the conclusions I have come to from the above detailed researches.

Although the general belief as to the nature of the aurora borealis certainly is that it is of electric origin,

other theories have been advanced, as for instance by Grönemann, *Astr. Nachr.*, 1874-75, and the reason of this is, I believe, that hitherto no direct proof had been obtained demonstrating its true nature.

But the experiments at Luosmavaara in 1871, *and at Oratunturi and Pietarintunturi in* 1882, *clearly and undeniably prove that the aurora borealis is an electric phenomenon.*

The science of the physical conditions of the globe has hitherto, particularly as regards the electric and magnetic ones, simply advanced by observing the effects of these great forces of nature, without however any successful attempt having ever been made to influence or call them forth either directly or indirectly. My experiments now, however, prove that *aurora borealis may be produced in nature* by a simple contrivance assisting the electric current flowing from the atmosphere to the earth. And although the efforts of man must always be limited in comparison with the grand products of nature, the conclusions which may be drawn from the same are not the less instructive.

In a question wherein the theoretical deductions, supported only by a few indirect proofs, have but slowly advanced, *absolute certainty* has now been obtained, and this result should induce future students of the aurora borealis not to devote attention to the "light" phenomenon itself, but to the investigation of those wonderful forces of nature the existence of which it so "lucidly" demonstrates. We have, of course, much to learn from the light also, but far more, I believe, from the electric forces which create it.

It is, however, far from my intention to insist that the apparatus invented by me is the best or that the method followed may not be improved on; still it has certainly one advantage, viz. that of being effective. It is, of course, evident that the drawbacks under which the experiments suffered—as, for instance, weak wires and defective insulators—must be remedied, and it appears to me that the theory which is the basis of M. Mascart's insulator would be particularly suited to the apparatus. The galvanometer should also be altered so as to consist of a *great* number of well insulated coils, in order better to regulate the deflexions, and the experiments should be made in a warm room. As the electrometrical method hitherto used gives only the electric tension at a certain point, it would, it appears to me, form a good meter for measuring the electric state of the surrounding atmosphere. The galvanometer deflexions depend certainly on the electric potential, as well as on the variable conducting power of the air; but it can, as will be seen from my experiments, be measured and even divided by using a constant galvanic element. The electric condition thus measured will give us *an idea* of the strength of the electric current, which in a certain place descends to the earth, and of the electric changes which take place in the atmosphere.

From the experiments with the terrestrial current described above it seems very probable that the current is closely related to the electricity in the auroral belt. The terrestrial current is, as is generally known, related to the magnetic variations, which is most conclusively shown by Mr. Airy's curves (*Phil. Trans.*, vol. cxxxviii. p. 465). In Sodankylä disturbances of the terrestrial current were always followed by a magnetic one. The exact result has of course not yet been calculated, but a glance at the figures returned is sufficient to show this. Mr. Airy's researches have caused these questions: (1) Are the variations in the terrestrial currents more numerous than the corresponding magnetic ones? (2) Do the terrestrial variations occur about half an hour from the corresponding magnetic disturbances?

We have from the experience gained attempted to explain these peculiarities, viz. by the hypothesis that the earth forms, so to say, the core in a flexible bobbin, represented by the terrestrial current circulating around her. In the first place, many of the changes to which the terrestrial current is subject could not affect the magnetic moment of the core, *i.e.* the earth; and, in the second place, the current acts directly on the instruments whereby the magnetic variations are measured; and in these circumstances we must find the explanation of the first-named peculiarity. With regard to the very remarkable difference in time of about *half an hour*, this is the exact time elapsing before the variations of the terrestrial current can affect the magnetic moment of the earth. It is, by the bye, only necessary to compare the duration of induction currents produced in bobbins with different iron cores, to observe that *half an hour* might well pass before the current became perceptible, *if the earth constituted the core.* In Polar regions the electric current descending from the atmosphere to the earth may also contribute to the variations which are measured by our instruments.

In accordance with this theory, therefore, the *electricity* which descends into the auroral belt is the *primary* cause of the greatest part of the terrestrial current, and, through this, of the many variations of the magnetic elements. There are also others, as the diurnal changes in the temperature on the earth's surface, but *the chief* cause is, in my opinion, the electric current from the atmosphere.

In my belief, therefore, the possibility of explaining the peculiarities of this phenomenon lies in a thorough and complete knowledge of the current from the atmosphere.

SELIM LEMSTRÖM
Professor of the Helsingfors University

(*To be continued.*)

THE FLORA OF ANCIENT EGYPT[1]

THE discovery made by Emil Brugsch Bey on July 6, 1881, in the vault of a king of the twentieth dynasty is of the greatest importance to botany in consequence of the large number of species of plants contained in the offerings and funeral repasts and in the wreaths which adorned the illustrious dead. Among them are several which were not known to belong to ancient Egypt. I have begun the study of the remains of these plants taken from the breasts of the most celebrated kings of Egypt and of such inestimable value to science. Deputed by Mr. Maspero to arrange these relics for the Egyptological Museum of Boulak, I have classified them according to the high personages for whom they were intended. On the eight cardboards which I have the honour to send you in the name of Mr. Maspero, you have a part of the funeral wreaths belonging to Ramses II., Amenhotep I., and Aahmes I.

The wreaths of Ramses II. were renewed towards the end of the twentieth dynasty (1100 or 1200 B.C.), or at the time of the twenty-first dynasty (1000 B.C.). The king of that period, according to records inscribed on the coffins and translated by Mr. Maspero, caused a new coffin to be made for the great Ramses, the one in which he had first been placed having been accidentally destroyed. In this new coffin were several yards of wreaths, which Mr. Maspero handed to me. I have examined them all and ascertained their composition.

The wreaths of Ramses II. are formed of the leaves of *Mimusops Schimperi*, Hochst., either folded or torn in

[1] "Memoir on the Discovery at Deir-el-Bahari in Relation to the Ancient Flora of Egypt," by G. Schweinfurth. [This article, written in French, was communicated to Sir Joseph D. Hooker by Dr. Schweinfurth, together with a set of the wreaths, flowers, &c., described therein. These objects were exhibited at the annual *soirée* of the Royal Society on the 25th ult., and are now on view in No. 3 Museum, Royal Gardens, Kew. With regard to the orthography of the names of the Egyptian kings, that employed by some of the leading Egyptologists of this country has been adopted in this translation. Thus Amenhotep has been substituted for what looks like Amenhotpan in Dr Schweinfurth's manuscript.—W. B HEMSLEY.]

See "La Trouvaille de Deir-el-Bahari." 20 photogr. par M. E Brugsch. Texte par G. Maspero. (Le Caire: chez F. Maurès et Cie., 1881.)

two and stitched together, and serving as clasps for the sepals and petals of *Nymphæa cærulea*, Savi, and *Nymphæa Lotus*, Hook., the whole strung on strips of the leaves of the date palm. Besides the wreaths, there were in the coffin at the side of the body, and fastened between the bands encircling the mummy, whole flowers of *Nymphæa cærulea* on stalks eighteen or twenty inches long. The water-lilies thus scattered separately on the mummy were all of the blue-flowered species. An examination of these entire flowers and the sepals and petals in the wreaths, whether of the white or of the blue-flowered species, leaves no doubt whatever respecting their identity with the living plants so common in ditches at the present day, especially in Lower Egypt, where they blossom from July to November.

The *Nymphæa cærulea*, Savi, which figures on all the ancient monuments of Egypt and among the offerings painted on the walls of the temples is often recognisable from the blue colour of its petals. In the temple of Ramses II. at Abydos the colour is remarkably well preserved, and be-ides there is always a leaf associated with each cluster of flowers, clearly demonstrating by its entire (not toothed) margin that the species represented is *N. cærulea* and not *N. Lotus*. The latter, whose sepals and petals occur abundantly in the wreaths taken from the coffins of Ramses II. and Amenhotep I., has not been found by me on the ancient monuments, though Unger records an instance at Beni Hassan where the white flower could be recognised. With regard to the question to which of the species the old name Lotus properly belongs, I have been able to ascertain the following facts. No design on the ancient monuments is referable to *Nelumbium;* neither the fruits nor the leaves, so easily characterised, are recognisable. Further, no remains of *Nelumbium* have been found either in the coffins or among the offerings and funeral repasts deposited in the vaults of the Pharaohs. The Lotus was not referred to *Nelumbium* until a very much later epoch. This plant has not been found among the wild plants of any part of Africa. It is eminently Asiatic, and was perhaps not introduced into Egypt before the Persian invasion. At the time of Ramadus it was probably cultivated every-

FIG. 1.—Portion of a Funeral Wreath from the tomb of Ramses II. (1000 to 1200 B.C.), composed of the folded leaves of *Mimusops Schimperi* and the petals of *Nymphæa cærulea*, Savi, stitched together with strips of the leaves of the Date Palm. A separate leaf of *Mimusops Schimperi*.

where in Egypt, for we often find it in the mosaics, sculptures, &c., of that period, associated with papyrus and animals characteristic of the Nile, and easily recognised by its fruit.

The most ancient writer who treats of the Egyptian Lotus in such a way as to leave no doubt that he meant the *Nelumbium*, and not a species of *Nymphæa*, is Herodotus (lib. ii. cap. 92); after him Theophrastus ("Hist. Plant." lib. iv.), and then Strabo, while Pliny (lib. xiii.) clearly alludes to a *Nymphæa* in a comparison of the fruit with the capsule of a poppy.

The *Mimusops* was evidently a sacred tree to the ancient Egyptians. The fruits, or the stones of the fruits, which had been eaten, are often found in the funeral repasts in the vaults; and the leaves not only occur in the wreaths of the ancient empire but likewise in those of later times, even down to the Græco-Roman epoch, as specimens in the Leyden Museum testify.

The fruit of *Mimusops* found in Egyptian tombs[1] exactly resembles—except that the stones are a little thicker—that of *M. Kummel*, Bruce, a species spread throughout Abyssinia and the region of the Upper Nile; yet no species of the genus is found wild in Egypt. The leaves forming the wreaths in question should belong to the same species as the fruits found in the tombs. Nevertheless, in comparing them with numerous specimens of *Mimusops Kummel*, I did not meet with the perfect identity one would have expected from the resemblance of the fruits. In Central Africa, and especially in Abyssinia, an allied species, *M. Schimperi*, exists, the leaves of which are much more like those of the wreaths. A longer, and especially a slenderer, weaker petiole, and a more acute, less abruptly acuminate blade characterise these leaves. With regard to the fruit of *M. Schimperi*, I have not had an opportunity of studying it. Moreover the two species under consideration are not sufficiently established as distinct species. But an anatomical character came to my aid. Dr. Westermaier of Berlin has ascertained that the leaves of *Mimusops Schimperi* and of *M. Elengi*, L., have a double layer of epidermal cells, a character they possess in common with the leaves from the ancient tombs; whereas in the leaves of *M. Kummel* there is only a single epidermal layer of cells.

[1] The ancient fruits, however, have usually a thicker stone, the three angles of which appear to be more prominent than in that of *M. Kummel*, Bruce.

Should this distinctive character be constant in the two African species, there is a double reason for naming the ancient *Mimusops M. Schimperi*. The fruit of *M. Elengi* is very distinct from that found in the tombs. I think it very likely that this species, of which we so often find the fruits and leaves in the tombs of the ancient Egyptians, may be the *Persea* of the old authors, which modern botanists have erroneously referred to *Balanites* and *Diospyros mespiliformis*.[1] The latter has not hitherto been found in the ancient tombs; neither does it occur depicted on the monuments. Diodorus (i. p. 34) has transmitted to us a valuable tradition concerning the *Persea*. He states that it was introduced into Egypt with the first colonists coming from Ethiopia, which clearly implies that the ancient authors regarded it as having been introduced from the regions of the Upper Nile and not as belonging to the indigenous flora. *Balanites*, however, grows wild in the valleys of the Eastern Thebaid and on the borders of the Red Sea, and in Nubia this shrub is of general dispersion. True its fruit has been found in the funeral repasts in the tombs, yet that of the *Mimusops* has been found much more frequently, and, in support of my hypothesis, the thick leaves of the *Balanites* are always wanting in the wreaths.

According to Theophrastus, the *Persea* had a black wood, and he compares the flowers with those of the apple-tree. I do not know the wood of the *Mimusops* sufficiently, but with regard to the flowers it must be admitted that no ancient authors ever made a more unmistakable comparison, while the flowers of the *Balanites* have nothing in common with those of the apple. Pliny (lib. xiii. p. 9) does not speak of the *Persea*, but of the *Persica*, and the only surprising thing in it is that he treats it as indigenous in Egypt. He mentions, too, the peculiarity of the Egyptian variety of the peach-tree, which consists in its persistent foliage. Even now in the middle of winter we see the peach-trees in blossom while still carrying their leaves. The same author (lib. xv. p. 13) expressly points out the difference between the *Persica* and the *Persea*. On Egyptian monuments we often see a tree diagrammatically represented, though the distichous, elliptical, acute leaves are evident. This tree, sacred to Hathor or Isis, and often drawn with these divinities, probably represent the *Mimusops* in question. The fruit of *Mimusops Kummel*, of Central Africa, resembles in appearance as well as in taste that of the wild rose; and it may be that under cultivation a still more palatable fruit could be obtained. Indeed, the fruit of specimens of this species collected in Abyssinia appears to be much more pulpy.

All the wreaths of the find at Deir-el-Bahari are of one and the same pattern. The leaves are folded lengthwise in the middle,[1] then folded again in the contrary direction over a string or strip about $\frac{1}{8}$ in. wide, of a leaf of the date-palm. In the fold of each leaf, single flowers, or parts of flowers (sepals and petals), are inserted in

FIG. 2.—Portion of a Funeral Wreath from the tomb of Amenhotep I. (1300 to 1700 B.C.), composed of the folded leaves of *Salix safsaf* and the flower-heads of *Acacia Nilotica* strung together with strips of the leaves of the Date Palm. A separate leaf of the *Salix* (the teeth represented too sharp) and a flower-head of the *Acacia*.

such a manner that they are fixed in the leaf as in a pair of pincers. Then with a finer strip of the date-leaf than the central one, they are stitched through and securely fastened together in long rows side by side, and all pointing in the same direction. These wreaths are arranged in semicircles on the breast of the mummy, so that their disposition is like one sees in the necklaces of the present day. Their thinness rendered them suitable for using in large numbers, and sometimes they occur in several layers one above the other, filling up the limited space between the mummy and the lid of the coffin.

It is probable that it is to this kind of wreath that Pliny alludes (lib. xxi. p. 2) as the "so-called Egyptian wreaths," of which Plutarch and Athenius praised the beauty. Unfortunately these wreaths, which, with ordinary care, might have been removed entire from the mummy when the coffin was first opened, were broken and reduced to powder in several places. The specimens I send you attached to cardboard are the most perfect that I could procure after those selected for the Museum of Boulak. On placing them in boiling or cold water, according to the species, the leaves, &c., recover their original flexibility, especially in *Nymphæa cærulea*; and with proper precaution one succeeds in spreading them out and drying them again effectually. The fragility of these objects is only due to the extreme state of dryness they have reached during the thirty to thirty-five centuries they have lain in the tombs. It is at the same time the principal factor in their wonderful preservation.

The wreaths of the other kings of this vault I have at present only partially examined. From their general appearance, however, as well as from the flowers and leaves of which they are composed, which also indicate a different season[2] of the year, one would be justified in attributing them to a different period from that during which the wreaths of Ramses II. were renewed. If they really date from the time when the bodies of the kings of the eighteenth dynasty were first deposited in the vault, we have here to do with specimens four or five centuries older than the wreaths of Ramses II. In any case these objects are at least contemporaneous with the time commonly assigned to the Trojan war, if not several centuries more ancient.

The wreaths of Amenhotep I. (who was found during

[1] Kunth took the stones of *Mimusops* found by Passalacqua to be this plant.

[It may be mentioned that Kunth published his determinations of the relics found by Passalacqua in the *Annales des Sciences Naturelles*, viii. (1826) p. 418. Unfortunately it is not known to what period they belonged. Among them were seeds of a palm, *Areca* (?) *Passalacquæ*, Kunth, which was subsequently identified by Unger with *Hyphæne Argun*, Mart., a palm which inhabits some of the valleys of the Nubian desert in the bend of the Nile between Korosko and Abou Hammed.—W. B. H.]

[1] Or when they were too large they were torn in two.

[2] The records to which I have alluded indicate the day and the month; and these flowers will one day serve to fix the season with which the month of that epoch coincides. The Carthamus could only be had from the end of March to the middle of May; the Water-lilies from July to November while the young leaves of Salix indicate the spring. The Acacia and Sesbania flower at all seasons.

the twentieth dynasty still intact in his coffin, and who, according to Brugsch, preceded Ramses II. by three centuries) are more varied. Among them are some composed, like those of Ramses II., of the leaves of *Mimusops* and the sepals and petals of the two species of *Nymphæa;* while others are formed of the leaves of *Salix safsaf*, Forsk., which serve as clasps for the little balls of flowers of *Acacia Nilotica*, Del., portions of the heads of flowers of *Carthamus tinctorius*, L., or the separate petals of *Alcea ficifolia*, Cav.

Nobody could recognise either the *Salix* or the *Alcea* among the hundred Egyptian species of plants enumerated by Pliny, or in the writings of other ancient authors; whereas the *Acacia* and the *Carthamus* occur under the names of *Acanthos* and *Cnicus*. Concerning the former, Pliny (lib. xiii. p. 19) mentions the employment of its wood in boat-building, the use of its gum, of its pods in tanning; he speaks of the spines, even, which are found on the leaves; in short he indicates the distinctive feature of the species, adding that the flowers are effective in wreaths. Several of the old authors treat of this tree. With regard to the *Cnicus* or *Knekos* (Pliny, xxi. p. 53) it is only recognisable by the indication that it is spiny, that its large white seeds yield an oil, and that there are in Egypt both wild and cultivated species, which is true. The flowers of *Carthamus* found in the wreaths of Amenhotep I. have retained their red colour, and resemble those of the species cultivated everywhere in Egypt at the present day. The colour, as in recent herbarium specimens, has changed from cadmium red to a brownish red or orange. In water the colouring matter is rapidly excreted, and we behold these flowers of some thirty to thirty-five centuries ago intensely colouring the liquid in the phial containing them.[1] All four of the plants which I have just mentioned have now for the first time been actually found in an ancient Egyptian tomb. The leaves of *Salix safsaf*, which form the greater part of the wreaths of Amenhotep I. and Aahmes I., do not differ in the least from those of the present day, and the species is common in Egypt. They are young—that is to say small and pale—thus indicating an early season of the year. In this respect they are in contradiction with the blue and white petals of *Nymphæa* found in the same coffin, though not, it should be stated, in the same wreaths as the *Salix*, but in the wreaths with leaves of *Mimusops*. The latter very closely resemble those found on the mummy of Ramses II. Perhaps at the time of the removal of the kings of the eighteenth and nineteenth dynasties from one vault to another, and finally to the place of concealment at Deir-el-Bahari, when a new coffin was made for Ramses II.—perhaps, I say, they renewed a part of the wreaths of the other kings, or having ascertained the condition of the mummies (whether under the twentieth or under the twenty-first dynasty), they added some new wreaths to the original ones. This would explain the presence in the same coffin of flowers belonging to different seasons of the year.

Salix safsaf, which occurs in a wild state on the banks of the Nile in Nubia, is in Egypt proper only a riverine fugitive, like many other plants, whose real home is in the south. Away from the river it only exists on sufferance, chiefly near wells and canals. To my mind it is an example of the wild flora which agriculture has caused to disappear. *Alcea ficifolia*, Cav., is now found in Egypt only in the ancient Arabian gardens of Cairo and other towns—that is to say, in gardens dating before the introduction of European horticulture by Barillet in 1869, where it grows almost wild as a weed. I have found it in a wild state in Syria and the Lebanon. Boissier, in his "Flora Orientalis," has not clearly defined it, and gives one or two other forms (*A. lavateræfolia*) as distinct species, which they are not. The petals of the *Alcea* contained in the wreaths of Amenhotep I. leave no doubt that they belong to the species named. Their shape, the distribution of the veins, and especially the hairy callosity on the inner surface of the claw, as well as the size even, confirm the identity of the species. Moreover one perceives in the petals of the ancient wreaths traces of a purplish tint corresponding to the crimson of the living plant. The ancients probably esteemed this plant alike for its beauty and its medicinal properties.

I have examined a head of flowers of *Acacia Nilotica* coming from one of the wreaths, and I found that the flowers agreed in the minutest details with fresh ones, with the characters of which I am sufficiently familiar. The proportions of the peduncle, the position of the annular bract, the shape of the bracteoles, the calyx, the petals, and stamens of each flower do not exhibit the slightest differences. This tree, which is planted or tolerated by man all over Egypt, is nowhere completely wild except on the White Nile between 11° and 12° N. lat., where it constitutes large riverine forests.

The wreaths which were found in the coffin of Aahmes I., the great founder of the eighteenth dynasty (1700 B.C., according to Brugsch), are the most varied, and astonish the eyes with the bright colours they have retained. They are partly composed of leaves of the Egyptian willow (*Salix safsaf*), containing separate flowers of *Delphinium orientale*, Gay, of *Sesbania Ægyptiaca*, Pers., petals of *Alcea ficifolia*, or flower-heads of *Acacia Nilotica;* and partly of the leaves of *Mimusops*, serving as clasps for the petals of the two species of *Nymphæa*, like the wreaths of Ramses II. and Amenhotep I. The *Delphinium* and the *Sesbania* had not hitherto been authenticated from ancient Egypt. The colours of their flowers are admirably preserved, the deep violet of the former being especially striking, but the specimens I have communicated to you in a phial of alcohol have lost their colour, just as fresh flowers of our time would. *Delphinium orientale* is now spread over a very wide area of the Mediterranean region. The two nearest localities to Egypt where it has been found are Algeria and Northern Syria, near Raldoun. It is not impossible that it still occurs in some parts of Egypt, while it is equally possible that it was cultivated by the ancient Egyptians as an ornamental plant. In the event of our being able to prove that some of the wreaths of Aahmes I. and Amenhotep I. were removed at the time of the twentieth dynasty, together with those of Ramses II., we should be justified in the assumption that this plant and *Alcea ficifolia* were introduced through the conquest of Syria. A minute analysis of the flowers, and comparison with those from various localities, leaves no doubt that they are of the species mentioned; and if I had had access to a larger number of flowers of the plant of the present period, I am certain that I should have been able to have exactly matched the ancient ones. The differences that I was able to detect between the ancient flowers and recent ones from Algeria, the Caucasus, Phrygia, and Lycia, kindly supplied by Mr. E. Boissier, may be set forth in a few words. In the first place there are two narrow linear bracteoles exceeding the peduncle in length, and reflexed; then the ovary is less pubescent, and the sepals are narrower and less acute. With regard to the bract, the thickened peduncle, the shape, number, and disposition of the stamens, the stigma, and especially the single petals, I have seen recent flowers in which these organs are absolutely identical. It will be seen that the characters in which they differ are only of individual value. Further, the species in question, commonly cultivated at the present time, comprises a considerable range of forms. Thus there are varieties in which the single petal is merely three-lobed, whilst in others the intermediate lobe is again divided. Both conditions occur in the ancient flowers. These flowers are so well

[1] Unger ("Botanische Streifzüge," p. 113) mentions that a chemist named Thomson had proved that the red dye in the mummy bandages was derived from *Carthamus*.

preserved that under the influence of boiling water the spur of the posterior sepal is easily separated from that of the petal projecting into it. That is to say, the latter may be extracted without injury. The numerous details of the petal, its intricate venation, the coloured glands on the margins, the claw with two lateral folds—all correspond to recent specimens. The colour of the ancient flowers is rather a deep bluish violet than a reddish violet, as in the plant of our time.

I have also carefully analysed the flowers of *Sesbania Ægyptiaca*, from the wreaths of Aahmes I. They belong to the typical form of the shrub, which still springs up on the borders of cultivated fields and on roadsides in Egypt, though it is not really spontaneous below the Soudan. The flowers are so perfectly preserved that the minutest detail did not escape my scrutiny. Submitted to the action of boiling water they scarcely differed from flowers taken from my herbarium. One circumstance shows how hurriedly these funeral wreaths were made. The flower torn from its pedicel and pinched with the finger nails always retains only a part of the calyx cut through the middle.

In the find at Deir-el-Bahari other objects besides the wreaths were found for the first time. Thus in the coffin of the priest Nibsoni, of the twentieth dynasty, the leaves of *Citrullus vulgaris* were scattered between the body of the mummy and the sides of the coffin; and flowers of *Nymphæa cærulea* were found fixed beneath the outer bandages of the same mummy. The Egyptian Museum of Berlin already possessed seeds of this *Citrullus* in the collection of Passalacqua, though the epoch to which the collection belongs is unknown. *Citrullus vulgaris* is found wild in the greater part of Central Africa,[1] and its fruit is smaller than that of the cultivated race, and less palatable, though otherwise like it. Among the broken remains in question I found one whole leaf, which enabled me to fully study its specific characters. Placed in cold water it recovered its original flexibility, so that it could be spread out flat and dried again. The chlorophyll was perfectly preserved, and what was curious, it was absorbed by the water to such a degree, that the glass of water in which the leaf and portions of leaves were placed became of an intense green colour. The problem to solve was whether the leaves were those of the water-melon or those of the colocynth, a species spread over the whole desert region, and only differing from the former, which has long hairs on the young fruit, by the complete nudity and spongy nature of its bitter fruit with a hard rind, and by the seeds. The leaves of the water-melon often very closely resemble those of the colocynth, especially in the variety called *Gjurma* (*Gyurma*) in Egypt, which bears fruit no larger than that of the colocynth, though it is always sweet. Nevertheless the large leaves of elongated outline and having less numerous lobes, are rare in the colocynth, and only in places well watered by rains. There is an association of characters in the leaves from the mummy of Nibsoni, that enable one to refer them to varieties of the cultivated water-melon, rather than to the wild colocynth. I have compared them with a long series of specimens of the water-melon from all parts of the Nilotic region, and with a no less numerous series of specimens of the colocynth; and I have come to the conclusion that they may be regarded as belonging to the former species. The uses of the two species would render them equally admissible in a coffin of ancient Egypt. As a funeral offering an alimentary plant might serve as well as a medicinal one. Still the fact that there are seeds of the water-melon in the Berlin Museum from an ancient tomb supports my first supposition. The leaves found on Nibsoni are about a palm long, and of a pinnatisect form, with obtuse lobes. If these leaves were distinctly hairy there would be no doubt of their belonging to the water-melon. Yet, as already mentioned, there is a variety widely spread in Egypt which has not the long and numerous hairs attached to the tubercles with which the leaves are covered, but merely short bristles, which is also the case in the colocynth.

This variety of water melon, which I have named *colocynthoides*, is the *Gyurma* of the Egyptians, and is cultivated in dry neglected ground in Upper Egypt. It is probably the primitive condition of the species before it had reached its present state of perfection. The leaves of the *Gyurma* are sometimes hairy, as in the water-melon, sometimes only provided with short deciduous bristles, as in the colocynth. The leaves from the coffin of Nibsoni exhibit only the latter condition. It may be that they have lost a great part of these deciduous hairs during the long period that has elapsed. I found one character, however, that the *Gyurma* has in common with those in question. There are on the petiole, and especially on the under surface of the leaf in the middle, among the round tubercles with which it is beset, other tubercles or callosities of an elongated linear form and arranged in rows corresponding to the secondary veins. On these leaves, as well as on those of the *Gyurma*, these elongated tubercles are much more prominent than they are in the colocynth. Moreover the numerous specimens that I have compared of the last have all of them leaves more densely furnished with the round tubercles than is the case with those of the water-melon, of the *Gyurma*, and the ancient leaves.

The secret vault of Deir-el-Bahari, besides the coffins of so many illustrious kings, also contained numerous funeral offerings deposited there by the later kings of the twenty-first dynasty who used this collective tomb, so well concealed by the topographical conditions. Among these offerings I was able to recognise dates, raisins, and pomegranates. There was also a basket filled with a lichen (*Parmelia furfuracea*, Ach.) which at the present day is sold in the bazaar of drugs in every town of Egypt. It is now called "Chêbi" (Sheba), and is used to leaven and flavour the Arabian bread. Medicinally, also, it is in great request. The presence of a lichen of solely Greek origin, mixed with the species named, and which also occurs in the modern drug, excludes all doubt as to its being a commercial product. *Ramalina Græca*, Muell., Arg., which was mixed with the *Parmelia*, has only been found in the islands of the Greek Archipelago, and the Arab merchants regard that country as the source of their drug. As there is no locality in Egypt where *Parmelia furfuracea* could grow, the only explanation of its presence in the offerings of the twenty-first dynasty (1000 B.C.) is that it was derived from Abyssinia or Greece. In the latter case the find at Deir-el-Bahari would prove the existence of commercial intercourse with Greece at about the time of the Trojan war. Among the *Parmelia* (which was perhaps the *Sphagnos* of Pliny) were fragments of *Usnea plicata*,[1] Hoffmg, and the straw of a grass (*Gymnanthelis lonigera*, Anders.) of Nubia, which at the present day is used by the natives as a remedy against affections of the chest and stomach. On searching through the copious remains of this plant I succeeded in finding a few well-preserved flower-spikes, which I carefully examined and determined beyond doubt to belong to the species mentioned. In Arabic it is called "*máhareb*." The odour even of this grass was preserved to a certain extent in the mixture of the offering. The fragrant secretion is of the same nature as that of the allied section *Schœnanthus* of *Andropogon* of India. Besides the lichens and the grass, this offering contained the hairy buds of some *Compositæ*, probably an *Artemisia*, with pinnatisect leaves; tendrils of some *Cucurbitaceæ*; seeds of the coriander; and numerous berries and seeds of the eastern Juniper (*Juniperus Phœnecia*). Inasmuch as we have here to do with plants coming from opposite regions of Africa and from Europe or Asia, it was

[1] I have gathered it in that state in the islands of the White Nile.

[1] Dr. J. Mueller of Geneva

not an easy matter to pronounce an opinion on the *Cucurbitaceæ* and the *Compositæ* mentioned. The coriander is a plant of early cultivation in Egypt, being mentioned by Pliny as one of the best products of the country. The berries and seeds of the juniper (the latter free in consequence of the decomposition of the former) could only have been derived from Syria or the Greek Islands. I carefully compared them with the allied species, including the Abyssinian *Juniperus excelsa* (which has larger berries and much thicker seeds, to the number of six), and there can be no doubt that they belong to *J. Phœnicea*, L. Kunth had previously determined this species in the collection of Passalacqua.

Among the fragments of the offerings and repasts found scattered on the floor of the vault of Deir-el-Bahari when it was first inspected by Brugsch Bey (some of the objects had already been disturbed by Arab robbers) was a tuber of *Cyperus esculentus*, L., some specimens of which from ancient Egypt are also preserved in the Berlin Museum. It is common in a wild state, and generally cultivated in the country.

In bringing this enumeration to a close I have only to mention the finding of a bundle of the grass called *Halfa* by the Egyptians (not the *Halfa* of Tripoli and Algeria), *Septochloa bipinnata*, Hochst., syn. *Eragrostis cynosuroides*, Retz. This bundle probably formed part of an offering representing the productions of the black and fertile soil of the valley of the Nile, of which this grass was a good sample.

ON THE CHEMICAL CHARACTERS OF THE VENOM OF SERPENTS

DRS. WEIR MITCHELL and E. T. Reichart, of Philadelphia, are now engaged in an inquiry into the chemical composition and characters of snake poison, which promises to yield important results and to supply information long wanted on an aspect of the subject which has made little progress since Prince Louis Lucien Bonaparte published his discovery of an active principle in viper venom, which he considered to be the sole cause of its toxic properties, and to which he gave the name of Echidnine or Viperine. He described the mode of separation of this principle in a paper read before the "Unione degli Scienziate Italiani" at Lucca in the year 1843.

The investigations of Drs. W. Mitchell and Reichart relate chiefly to crotaline snake poison, but include a partial analysis of some dried cobra (colubrine) poison sent to them by Mr. V. Richards from India.

Difference in the mode of action of the colubrine and viperine virus was pointed out by me many years ago in India, when I observed that viperine poison destroys the coagulability of the blood in animals, causes hæmorrhage, and has peculiar effects on the nervous system differing from the cobra's (colubrine) venom, which does not destroy the coagulability of the blood, nor cause so much hæmorrhage.

Dr. Wall of the Bengal Medical Service has added much to our information on the subject, and has defined the different modes of action of the venom of the principal Indian poisonous snakes.

The Philadelphia observers came to the conclusion that the venom of the crotaline snakes with which they have chiefly operated can be subjected to the action of the boiling temperature of water without completely losing its poisonous power. The toxicity of the venom, however, of the *Crotalus adamanteus* seems to be destroyed by a temperature below 176° F. Mitchell some years ago showed that the venom of *Crotalus durissus* is not destroyed by boiling, and they remark on the curious fact that the venom of *C. adamanteus* should thus differ from the venom of other snakes.

The symptoms caused by the venom of the different snakes with which they have operated do not, they say, differ radically save in degree, but there are certain symptoms which they think make it probable that further investigation will enable them to point out certain differences by which it will be possible to discriminate one form of poisoning from the other. This is in accordance with what has already been done by observers in India, and notably by Dr. Wall.

The investigations of Drs. Weir Mitchell and Reichart so far, lead them to conclude that the poison of the cobra is the most active, next the copperhead, then the moccasin, and lastly the rattlesnake; but their researches on this head are not yet complete.

They are unable to confirm the statement of Gautier of Paris that an alkaloid resembling a ptomaine exists in cobra poison; or that of Prof. Wolcott Gibbs, that the poison of crotalus yields an alkaloid; but they have satisfied themselves that the venom contains three distinct proteid bodies, two of which are soluble in distilled water, one which is not soluble. These bodies have certain properties and reactions, which are detailed in their monograph on the subject.

Hitherto observers have regarded the venom of different snakes as each representing a single poison, but it appears from these researches that, of the three proteids before mentioned, one is analogous to peptone and is a putrefacient poison, another is allied to globulin, and is a most fatal poison, probably attacking the respiratory centres and destroying the power of the blood to clot, while the third resembles albumen, and is probably innocuous. The separation of the two poisons necessitates a long and elaborate series of researches, the results of which will be subsequently reported.

They have also ascertained that the poison of the Rattlesnake (*Crotalus adamanteus*), Copperhead (*Trigonocephalus contortrix*), and Moccasin (*Toxicophis piscivorus*), are destroyed by bromine, iodine, hydrobromic acid (33 per cent.), sodium hydrate, and potassium permanganate. It is to be hoped that these important and valuable researches will be continued until the true chemical nature of these poisons be completely made known.

J. FAYRER

NOTES

AT a meeting of the subscribers to the Balfour Memorial Fund, held at Cambridge on the 26th inst., it was stated that 8309*l.* had been promised, all except 100*l.* of which had been paid. Of this 8078*l.* had been invested, yielding an annual income of 284*l.* 10*s.*, which it was hoped further subscriptions would raise to 300*l.* Among the regulations agreed to were the following:—The income of the fund shall be applied (1) to endow a Studentship the holder of which shall devote himself to original research in biology, especially animal morphology; (2) to further by occasional grants of money, original research in the same subject. The Student shall not necessarily be a member of the University, and during his tenure of the Studentship shall devote himself to original biological inquiry, and shall not systematically follow any business or profession or engage in any educational or other work which in the opinion of those charged with the administration of the fund would interfere with his original inquiries. The place and nature of the studies of the Student shall be subject to the approval of the managers provided that the Student shall be bound to pursue his studies within the University during at least three terms during his tenure of the Studentship, unless the managers shall, with the approval of the Board, dispense with this requirement for special reasons. The managers shall take such steps as they may think necessary to satisfy themselves as to the diligence and progress of the Student, and may require from him any reports or other information on the subject of his studies which they may think desirable. The Studentship

shall be tenable for three years, but it may be continued over a second term of three years (but no longer) to the same person if the managers and Board decide that it would be clearly in the interests of biological research. The balance of the income of the fund, after providing for the Studentship and for any necessary expenses connected with the election, shall be devoted to the furtherance of original research in biology, especially animal morphology. Grants may be made for this purpose either to the holder of the Balfour Studentship or to any other person engaged in research.

THE subscription list for the memorial bust of Prof. Henry Smith, to be placed in the University Museum, will be closed at the end of the present term. It would be convenient if subscribers would, as soon as possible, pay their subscriptions into the Old Bank, or send cheques to any of the following gentlemen :—Mr. W. Little, Queen Anne's Mansions, S.W.; Mr. R. L. Nettleship, Balliol College, Oxford; or Mr. E. Chapman, Frewen Hall, Oxford.

DR. JULIUS VON HAAST has been created a Companion of the Order of St. Michael and St. George.

TWO statues which have been erected in front of the Berlin University to the Brothers Alexander and Wilhelm von Humboldt were unveiled on Monday with great ceremony. The Emperor and some of the members of the Imperial family witnessed the proceedings from the Royal Palace, which immediately faces the University, and the Emperor afterwards went on foot to inspect the statues.

DR. GABRIEL GUSTAV VALENTIN, one of the most eminent professors of the University of Berne, and a distinguished physician, died at that city on May 24. Dr. Valentin was born at Breslau in 1810, graduated in 1832, and began practice in his native town in the following year. In 1835 he published a handbook of the history of evolution ("Entwicklungsgeschichte"), and in 1836 was appointed Professor of Physiology in the University of Berne, a position which he held until 1881, when ill health compelled him to resign. He stood very high in his profession, and was the author of many scientific works, two of which were written in Latin, "De phænomeno generali et fundamentali motus vibratorii continui" and "De functionibus nervorum cerebralium et nervi sympathici libri quatuor." He wrote also a "Text-Book of Physiology," a book entitled "Groundwork of Human Physiology," a "Repertory of Anatomy and Physiology," an "Examination of the Effects of Polarised Light on the Life of Plants," an elaborate work on the "Adaptation of the Spectroscope to Physiological and Medicinal Purposes," and several others which attest his vast knowledge and untiring industry.

THE following remarks by our American contemporary, *Science*, on the subject of the Canadian meeting of the British Association in 1884, are deserving of attention :—"It is to be observed that in the present year the meeting of the American Association, at Minneapolis, is early (August 17); while that of the British Association, at Southport, which is, besides, in the immediate vicinity of Liverpool, is unusually late (September 19). This will allow members of the American Association to attend both meetings, and it is stated that the retiring President of the American Association, and possibly others of its members, may avail themselves of this privilege. This may possibly permit arrangements to be made which might substantially unite the meetings of the two Associations in 1884, and so prepare for an international meeting in the future. If the meeting of the American Association for 1884 can be fixed for some northeastern city, sufficiently near to Montreal, and can be timed so as to occur a week before or after that of the British Association, there can be no doubt that a great number of the members of the latter body would take advantage of the opportunity to enjoy the companionship of their American *confrères*, while, on the other hand, many of these would gladly spend a few days at the meeting of the British Association. In this way it would seem that a greater benefit to science might result than even from an international meeting. There would be time for the complete transaction of the business of both Associations. Neither would suffer, either pecuniarily or in the value of its proceedings; and there would be the best possible opportunity for interchange of ideas between the scientific men of the United States, Great Britain, and Canada. Nor is it unlikely that some scientific workers from the continent of Europe and elsewhere may be attracted by a combination so unusual. It may thus be hoped that the proposed meeting of the British Association in Canada may not only be one of the most successful that this mother of Associations has held, but may inaugurate an epoch of renewed activity and progress in the widely-spread scientific work of the two great Associations of the English-speaking race."

THE New Parkes Museum of Hygiene at 74*a*, Margaret Street, Regent Street, was opened on Saturday under favourable and distinguished auspices. The Duke of Albany presided and formally opened the Museum, and gave besides a sensible and thoughtful speech. "Hygiene," His Royal Highness said, "as we now understand it, is a branch of knowledge of modern growth. It is one of the natural results of the great advance of science which this century has witnessed, and might, I fancy, not inaptly be defined as the application of scientific principles to the varying conditions under which we are called upon to live. Thanks to the labours of many eminent men, we have now advanced some way towards an accurate knowledge of the conditions which are necessary for health; and most of these conditions have long been familiar to the few. One object of the Parkes Museum will be to make them familiar to the many. We have learned, and are daily learning, that many of the luxuries and conveniences of modern life may become sources of danger to us if they be ignorantly used. London would be almost uninhabitable were it not for its wonderful system of sewers; but while enjoying the blessing of effective sewerage, we have had to encounter the difficulty of keeping the air of the sewers out of our dwellings. We all appreciate the brilliant light which is given by a gas lamp; but its wholesome use, we are now beginning to find, involves questions of ventilation which scarcely troubled those who were content with the comparative dimness of a candle. Again, the open coal fire has long been regarded as one of the chief luxuries of the Briton, but the collected smoke of the fires of 4,000,000 of people has become a nuisance too grievous to be borne, and one for which a remedy must be sought. It is notorious that many of our public and private buildings in this country have been constructed without due attention, or, indeed, any attention, to those details which alone make a dwelling wholesome. The experiences of my own family in this matter have indeed been singularly hard. We hope that this museum will tend to hasten the end of this state of things, and that henceforward 'healthiness' will be considered as an essential condition of true architectural beauty. For the healthiness of our dwellings we have to depend, not only upon the master mind which furnishes the plan, but even to a greater extent upon the intelligent hands of those who are called upon to carry out the details. Unless the work of these latter be done with intelligence and faithful honesty, the schemes of the wisest architect avail us little. The instruction which has been and will be given here to the artisans who carry out the sanitary details of our houses must be productive of good results. At least, let us hope that some of the specimens of defective workmanship to be found upon our shelves will impress upon them that death, disease, and sorrow may be the results of ignorance or carelessness on their part." Among the other speakers

were Sir Charles Dilke, Prof. Tyndall, and the Archbishop of York. It is to be hoped that the public, and especially those on whose skill and honesty our sanitary arrangements are dependent, will take ample advantage of the opportunities offered by the new museum.

THE seventh Congress of Russian Naturalists and Physicians will be held this year at Odessa, from August 30 to Sept. 9.

THE district of Pergamos in Asia Minor is now so infested with sparrows that application has been made to the Turkish Government for aid against them. It will be remembered that this district is subject to occasional invasions of rodents.

THE Marine Excursion Committee of the Birmingham Natural History and Microscopical Society announce that, in response to a wish expressed by many members, they have arranged a second excursion to Oban and the West Highlands of Scotland, similar to that which proved so successful in the year 1881. The party will leave on Friday, June 29 next, to reach Oban about 5 p.m. on Saturday. The screw steam yacht *Aerolite*, of about sixty tons, has been hired of Messrs. Ross and Marshall of Greenock for a week, commencing Monday, July 2; facilities will thus be afforded for dredging excursions not only in the district previously worked, but also in distant localities. Arrangements are being made for excursions to several places of interest in the neighbourhood of Oban.

THE sixth annual meeting and *conversazione* of the Midland Union of Natural History Societies will be held at Tamworth on June 12 next. Excursions have been arranged for that day and the 13th. The Darwin Gold Medal for 1882 will be presented to Prof. A. M. Marshall and W. P. Marshall, for their paper on the Pennatulida.

THE additions to the Zoological Society's Gardens during the past week include a Malbrouck Monkey (*Cercopithecus cynosurus*) from West Africa, presented by Mr C. D. Gordon; two Grisons (*Galictis vittata*) from South America, presented by Mr. Percy Kenyon Slaney; two Sloth Bears (*Melursus labiatus*) from India, presented by Mr. F. A. Curteis; a Surucucu or Bushmaster (*Lachesis mutus*) from Pernambuco, presented by Mr. J. Y. Barkley; a Common Chameleon (*Chamæleon vulgaris*) from North Africa, presented by Mr. Henry W. Weguelin; a Chimpanzee (*Anthropopithecus troglodytes* ♂) from West Africa, two Welsh Sheep (*Ovis aries*) from Wales, a Goffin's Cockatoo (*Cacatua goffini*) from Queensland, five Margined Tortoises (*Testudo marginatus*), thirteen European Pond Tortoises (*Emys europæa*), South European, deposited; a Common Seal (*Phoca vitulina*) from British Seas, a Grey-headed Porphyrio (*Porphyrio poliocephalus*), a Conical Worm Snake (*Gongylophis conicus*) from India, purchased; a Hybrid Tapir, ♀ (bred between *Tapirus roulini* ♂ and *Tapirus americanus* ♀), born in the Gardens.

OUR ASTRONOMICAL COLUMN

THE MINOR PLANET, ANDROMACHE.—Among the small planets mentioned in the last volume of the *Berliner Astronomisches Jahrbuch* as having been observed at one opposition only, though several oppositions have taken place since their discovery, is No. 175, detected by the late Prof. Watson of Ann Arbor, U.S., on October 1, 1877, and named *Andromache*. The orbit has a considerable eccentricity, and the planet recedes to a greater distance from the sun at aphelion than is the case with any other member of this now numerous group so far calculated; indeed at this point of its orbit it is distant from the sun 4·723 (the earth's mean distance being taken as unity), and only 0·594 from the orbit of Jupiter. There should be no great difficulty in recovering this planet during the month of June or July. According to the most accurate elements calculated by Prof. Watson it will be in perihelion about July 25, and in opposition a fortnight earlier, its computed intensity of light being equal to that of a star of fully the ninth magnitude. Its considerable south declination will give an advantage to a search at one of the observatories of southern Europe. To facilitate its reobservation we subjoin positions deduced from the orbit last published:—

At Greenwich Midnight

	R.A. h. m.		Decl. ° ′		Log. Distance from Earth.		Sun.
June 4	... 19 40·3	...	−27 23	...	0·1547	...	0·3635
12	... 19 39·0	...	27 44	...	0·1368	...	0·3622
20	... 19 36·0	...	28 7	...	0·1222	...	0·3610
28	... 19 31·5	...	28 29	...	0·1117	...	0·3600
July 6	... 19 25·9	...	28 48	...	0·1059	...	0·3594
14	... 19 19·9	...	−29 1	...	0·1055	...	0·3590

The planet will probably be situated at some distance in R.A. from these positions, which are only intended as an approximate indication of its places. The last reference to a search for it which we find in the circulars of the *Berliner Jahrbuch*, occurs in No. 118 (Correspondenz), 1881, March 3, where we read, "*Andromache* innerhalb −6m. 30s. bis −3m. 55s., und −2m. 20s. bis +4m. 15s. vergeblich gesucht." A special rough chart of stars in the vicinity to the tenth magnitude inclusive would be readily formed with the stars in the Bonn and Washington Zones as reference points.

THE GREAT COMET OF 1882.—M. W. Fabritius of Kieff has calculated the following elliptical elements of this comet from two normal positions for September 9 and October 6, and an observation at Königsberg on March 3 in the present year:—

Perihelion passage, 1882, September 17·2753 M.T. at Berlin.

Longitude of perihelion	276° 28′ 40″·1	M. Eq. 1882·0
,, ascending node	345 58 4·1	
Inclination	38 0 44·7	
Log. $(1-e)$	5·938209	
Log. semi-axis major	1·943548	
Log. perihelion distance	7·881757	

Motion—retrograde.

The corresponding period of revolution is a little less than 823 years, and as M. Fabritius attaches some weight to his result, he thinks the comet must have appeared about the middle of the eleventh century.

We shall doubtless have in due course a thorough discussion of all reliable observations; those made since September 30, when the disintegration of the nucleus commenced, will need special treatment.

THE OBLIQUITY OF THE ECLIPTIC.—In NATURE, vol. xxvii. p. 618, we quoted 23° 41′·1 as the value of the obliquity of the ecliptic at the assigned epoch of Ptolemy's catalogue. With reference to this statement Mr. W. J. Cockburn Muir, of Melrose, N.B., has made a discovery, on which he writes us as follows:—"In NATURE of April 26, at p. 618, I read that the 'obliquity of the Ecliptic' is 23° 41′·1, and I wondered much what had suddenly happened in the Kosmos. So I took means to ascertain from the Royal Observatory of Greenwich how the record stands, and I am comforted to find that, by the determinations in 1882, the earth's axis still remains at home—23° 27′ 16″·8." Our correspondent may be referred to any elementary treatise on astronomy.

GEOGRAPHICAL NOTES

MR. OSCAR DICKSON's Greenland Expedition, under the command of Baron Nordenskjöld, sailed from Gothenburg in the *Sofia*, 180 tons, 65 horse-power, drawing 10 feet, and of 11 knots speed, navigated by Capt. Nilsson and a crew of 13 men. With Baron Nordenskjöld are Dr. Nathorst, geologist; Dr. Berlin, doctor and botanist; Dr. Forsstrand, zoologist; Dr. Hamberg, hydrographer; Herr Kolthoff, zoologist; Herr Kjellström, typographer and photographer; two Laplanders, two Norwegian icemasters, and one harpooner. There is on board a complete scientific equipment and 14 months' provisions for subsistence on the inland ice. Eight or nine picked men accompany Baron Nordenskjöld. Count Stromfeldt, botanist; Dr. Arpi, archæologist and philologist; and Herr Flink, mineralogist, will disembark on the coast of Iceland for the purposes of

study and collection. The *Sofia* called at Thurso for coal on Sanday and left on Tuesday.

In connection with Prof. Fries' suggestion of colonising Greenland by mountain Lapps, to which we referred last week, we learn that Baron Nordenskjöld takes with him to Greenland two Lapps from Jockmock, to give their opinion of the country. One of them is thirty, and the other thirty-three years of age.

We learn from the last annual report of the East Siberian branch of the Russian Geographical Society that this Society, which has contributed so largely to the increase of our knowledge of Siberia, is beginning to recover from the losses it sustained during the great fire at Irkutsk. Private subscriptions have been raised for the reconstitution of the library and museum to the amount of 2170*l.*, and both are in a fair way of development. The library already has about 4000 volumes, but is in great want of foreign geographical publications, and makes an appeal to the geographical societies throughout the world to send their publications and, if possible, series of former publications, which ought to be addressed to the Secretary of the East Siberian branch at Irkutsk. The chief occupations of the Society were: the geological exploration east of Lake Baikal, by M. Chersky, who has already published a map of the western coast of the lake; archæological researches as to the prehistoric inhabitants of Siberia, by MM. Agapitoff, Khangaloff, Witkovsky, and Bogolubskiy; and the part it took in the organisation of the Arctic Meteorological Station at the mouth of the Lena, and of a series of four intermediate stations between Irkutsk and this station. This last scheme could not be realised in full, but two stations have already been opened at Verkholensk and at Preobrajenskoye. The last number of the *Journal* of the Society contains, besides the annual report and the proceedings, a list of new determinations of latitudes and longitudes in Transbaikalia; a notice on Shamanism with Yakuts; a paper on the populations of the basin of the Amur, according to Prof. Schrenck; a paper on the inscriptions on stones and rocks in the district of Minusinsk; and several notes, on the Lena Meteorological Station, on the Usuri region, &c.

Petermann's Mittheilungen for May contains a paper by Mr. Carl Bock describing a journey recently made by him from Bankok to the frontiers of the independent Shan States. He travelled along the Menam River in a boat given him by the Siamese Government, as far as Raheng, where he diverged into the Me Ping. He then proceeded partly by the river, partly by land through Lakon and Lampun, to a town which he calls Tschengmai, but which is more generally known as Kiangmai, or Zimmé. This place, which is the capital of the Shan States tributary to Siam, is an important point in Mr. Colquhoun's proposed railway from Rangoon and Moulmein, into south-western China. It formed the proposed terminus, too, of that gentleman's recent journey through Yunnan and the Shan States. Mr. Bock described it as a fortified town of about 700,000 people, lying in a fertile plain of uninterrupted rice fields, about 500 yards from the Me Ping, which is here 400 feet wide. Even now it is of great political and commercial importance, as it controls the trade of these regions both with Siam and with British Burmah. The teak forests of the States he describes as almost inexhaustible, especially higher up near the Meikong, where, however, it is not yet known whether the lumber can be easily floated down to the sea. For this purpose Mr. Bock recommends a careful survey of the various rivers and their tributaries. From Zimme he continued his way higher up to Kiangtsen, in the valley of the Meikong, and on the borders of the independent Shan States. It was his original intention to travel through these States into Yunnan, as it was Mr. Colquhoun's to travel through them from Yunnan, southwards. Failing this, he returned to the Me Ping, with the object of tracing this river to its source. He was prevented from carrying out either project by the native hostility, which, we regret to say, Mr. Bock himself did much to intensify, if not arouse, by his indiscreet behaviour. It would be inconceivable, if we did not have it on his own testimony, that any traveller among a people who, as he was specially warned, disliked even the Siamese, and absolutely hated any white man, should so far forget all discretion as to enter a populous town and "out of his own hand," as he describes it, take possession of the court of justice, and assault with a stick the official who endeavoured to prevent this unjustifiable trespass. He was punished by several days' imprisonment, but it is unfortunate for the cause of science that the hostility thus carelessly and wilfully aroused should have put a speedy termination to a journey full of promise. Mr. Bock, however, has shown beyond doubt that a railway from Bankok to the Shan frontiers is a possibility. It would pass through populous and rich districts in the valleys of the Menam and Me Ping. He says that no one who has not visited Zimmé can understand how extensive the trade of the place is, and his proposed railway would place the Laos States in direct communication with the sea, and attract the commerce not only of the Shan States, but also of Yunnan. These are exactly the arguments by which Mr. Colquhoun supports his scheme for a railway to Rangoon. Let us hope that in days to come, when this colossal project is an accomplished fact, there may be no dispute as to the originator of the idea of attracting the trade of south-western China to the sea by means of a railway through the Shan States.

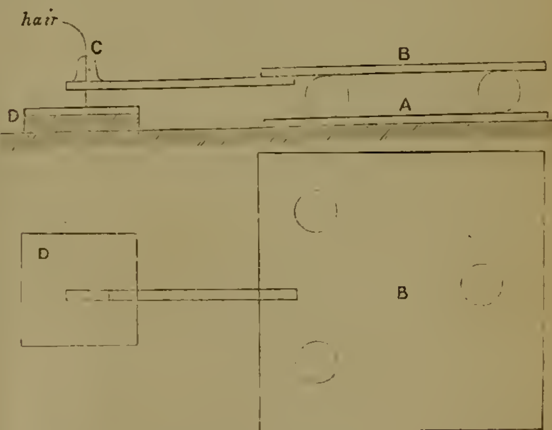
A NEW FORM OF SEISMOGRAPH[1]

Numerous forms of seismometers have from time to time been invented, and having these various instruments, it may be asked why there is any necessity for a new form, and I can best answer this by quoting from a report of a committee of the British Association of 1872, as follows:—"Some simple and cheap method of indicating earthquake movement is thus much to be desired—any apparatus for the purpose should occupy small space, be little liable to derangement, capable of being put up in any apartment not of special construction, and its indications such as any intelligent person could easily interpret and readily note."

Now none of the instruments yet invented fulfil these conditions, and hence I bring before you one which is of the very simplest nature.

The idea of the instrument I propose was suggested to me by the aseismatic arrangement designed by my father, Mr. David Stevenson, for averting damage to buildings and lighthouse apparatus in countries subject to earthquakes (*Trans. Roy. Scot. Soc. Arts.* vol. vii.).

The instrument is shown below, and consists of a ground and polished glass plate (A), about 5 inches square, placed level (once for all), on which rest three accurately turned ivory balls about $1\frac{1}{2}$ inch diameter, and on the top of these



balls is placed a plate (B) similar to the lower, but having attached to it a projecting arm with a long vertical hole pierced through it. Through this hole passes a steel needle (C) with a fine point, which rests by its own weight on a lampblack surface formed on the plate D. A hair about 2 inches long should be fixed to the eye of the needle to assist in adjusting it. The instrument thus becomes a pendulum of infinite length, so that whenever there is any movement of the ground, and therefore of the lower plates, the top plate with its arm and needle attached remain practically steady, and the point of the needle therefore marks on the lampblack surface the amount of motion and the direction in which the lower plate is moved. This instrument, it will be observed, fulfils all the requirements mentioned in the report of the committee of the British Associa-

[1] Abstract of paper read before the Royal Scottish Society of Arts, February 13, 1882, by Charles A. Stevenson, C.E., Edinburgh.

tion, and can be made more or less sensitive. It is impossible from a mere description to form any conception of the efficiency of the apparatus, nor has it been tried by any earthquake, but the instrument before you having been erected on the gable of a dwelling house during the past year, repeatedly registered the shaking of the gable to the amount of 1-16th of an inch.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE

CAMBRIDGE.—The Museums and Lecture Rooms Syndicate have just issued their annual report, in which they mention the high value of the present of the late Prof. Balfour's scientific instruments and library to the University by his family, and again emphasise the necessity existing for a new chemical laboratory. Mr. Clark records the mounting of the fine male Indian elephant's skeleton in the Zoological Museum, received in an exceedingly complete state last year in consequence of its careful preparation by Mr. A. Haly of the Colombo Museum. The animal was shot by Mr. Le Mesurier of the Ceylon Civil Service; its height was nine feet. A specially interesting skeleton of the adult Gangetic Dolphin has been presented by Sir J. Fayrer. Mr. A. P. Maudslay, M.A., of Trinity Hall, has deposited in Mr. Clark's care a large portion of his ethnological collection made in Fiji and adjacent islands; these are almost certain to be presented to the University at no distant date. The Curator in Zoology (Mr. A. H. Cooke) has catalogued and arranged the British species in the MacAndrew collection. Its completeness may be judged by the facts that of 6 recorded species of Brachiopoda this contains 5; of 159 marine Conchifera this contains 146; of 248 marine Gasteropoda this contains 208; of 125 land and freshwater shells this contains 114 A recent appeal to add missing species has already resulted in the presentation of fourteen species by Mr. J. T. Marshall.

Dr. Michael Foster reports an average class of about 100 in Elementary Physiology, and of over 20 in advanced Physiology, in the three terms of the past year. Additional lecture room accommodation is much needed for these large classes.

The morphological work begun by the late Prof. Balfour has been continued on the same lines by Mr. Adam Sedgwick, Mr. W. H. Caldwell and Dr. Hans Gadow as lecturers, and Mr. Walter Heape and Mr. W. F. R. Weldon as demonstrators. In the Lent Term of this year 63 students attended the elementary class, and 26 the advanced classes. Five students have been engaged in original work. Mr. A. J. Balfour, M.P., has offered to give annually a sum sufficient to defray the cost of the complete series of scientific journals taken in by his late brother.

Dr. Vines has carried on practical instruction in Vegetable Anatomy and Physiology under considerable difficulties owing to the small space available; he has had to repeat all the work four times. The numbers attending his practical classes in the Michaelmas Term, 1882, were 19; in the Lent Term, 1883, 37; in the present Easter Term, 35.

Prof. Hughes reports that the whole of the geological library, consisting of 800 volumes and 1000 pamphlets, of the late Mr. E. B. Tawney, have been liberally presented to the Woodwardian Museum by his brother, Mr. C. H. Tawney, late Fellow of Trinity College. Opportunity has been taken in the past year to largely improve the foreign Tertiary collections in the museum.

Prof. Stuart reports the addition of a number of machines and a large development of his classes; a foundry begun as an experiment has proved one of the most successful parts of his undertaking.

The Philosophical Library in the new Museums has been largely increased by the valuable presents made by the family of the late Prof. Balfour, by Mr. J. W. Clark, by Prof. Darwin, Prof. Humphry, Prof. Newton, and others.

It has been recommended by the Special Board for History and Archæology that a separate Board be created for Archæology, distinct from that of History. This has been concurred in by the General Board of Studies.

The Botanic Garden Syndicate have reported many improvements in the collections of trees, of rock vegetation, and in the Plant Houses. The largest specimens in the Palm House have been safely lowered to about 2½ feet below the ground level. All the genera of carnivorous plants in cultivation and most of the species are now in the collection. *Vitis gongylodes* has been flowered for the first time in this country. The Curator, Mr. Lynch, was deputed to visit the Botanic Gardens at Dublin, Manchester, and Liverpool, and has also visited Chatsworth with the result that much valuable information has been obtained in all departments of management and cultivation, and many important exchanges have been made.

The Adams Prize, for a general investigation of the action upon each other of two closed vortices in a perfect, incompressible fluid, has been awarded to Mr. J. J. Thomson, M.A., Fellow of Trinity College.

Messrs. W. H. Besant and E. J. Routh are the first to be notified as "approved by the general Board of Studies for the Degree of Doctor in Science."

Candidates for the Professorships of Physiology and Anatomy are requested to send their names to the Vice-Chancellor on or before June 7.

THE Institute of Agriculture, South Kensington, will give an extended series of lectures next winter, beginning on October 1. The following courses are arranged for:—Mr. Bernard Dyer, Chemistry in Relation to the Soil; Mr. F. Cheshire, Practical Course on the Use of the Microscope (these two courses to be delivered in the Lecture Theatre of the Museum of Geology, Jermyn Street). The next series will be given in the Lecture Room of the Natural History Museum, South Kensington: Mr. Bettany, Vegetable Physiology; Mr. Worthington Smith, Diseases of Farm Crops; Prof. J. W. Axe, Animal Physiology in Relation to Farm Stock; Miss E. A. Ormerod, Farm Insects; Mr. W. Topley, Geology and Physical Geography in Relation to Agriculture. The remaining courses will be given in the Lecture Theatre of the South Kensington Museum: Prof. Tuson, the Chemistry of the Food of Farm Stock; Prof. Buckman, Farm Seeds; Prof. Tanner, Agriculture; Mr. R. Holland, Management of Grass Land; Mr. Gilbert Murray, Breeding and Management of Horses; Mr. W. Housman, Cattle; Mr. H. Woods, and Mr. J. A. Clarke, Sheep; Prof. J. W. Axe, Preventable Diseases of Farm Stock; Farm Implements and Machinery, Mr. W. R. Bousfield and Mr. W. W. Beaumont. A distinct course of lectures will be given on Poultry, Dairy, and Bee Management. The arrangements made enable students to give their undivided attention to one subject at a time, two lectures being given daily till the subject is completed. The fees being at the rate of half a guinea for each week's course of ten lectures, and any student being allowed to attend a single course, the greatest facility exists for persons choosing their work according to their needs or convenience. Thus it is believed, after the success of the tentative courses of the past winter, that many sons of tenant farmers will find this a most valuable and available mode of acquiring an agricultural education.

SCIENTIFIC SERIALS

THE *American Naturalist* for March, 1883, contains:—On the extinct dogs of North America, by E. D. Cope.—On the plains of Michigan, by V. M. Spalding.—Organic physics, by Charles Morris.—Indian music, by E. A. Barber.—On the occurrence of fossiliferous strata in the lower Ponent (Catskill) group of Middle Pennsylvania, by E. W. Claypole.—Pitcher plants, by Joseph F. James.

April, 1833, contains:—The Naturalist Brazilian Expedition, No. 1, from Rio de Janeiro to Porto Alegre, by H. S. Smith.—Unnatural attachments among animals, by J. D. Caton.—Butterfly hunting in the desert, by W. G. Wright—The extinct Rodentia of North America, by E. D. Cope.—Heterogenetic development in Diaptomus, by C. L. Herrick.—A study of the immature plumage of the North American shrikes to show their descent from a common progenitor, by Thos. H. Streets.

May, 1883, contains:—Wampum and its history, by E. Ingersoll.—The Naturalist Brazilian Expedition, No. 2, by H. S. Smith.—The Polar organisation of animals, by C. Morris.—On the classification of moths, by A. R. Grote.—Heterogenetic development of Diaptomus, by C. L. Herrick.—On the morphology of arteries, especially those of the limbs, by F. Baker.—The hairy woodpecker, by A. G. Van Aken.

Archives Italiennes de Biologie, tome ii. fasc. 2, November 30, 1882, contains among the original articles the following:—On the minute anatomy of the muscles which move the wings of insects, by G. V. Ciaccio.—On the structure of striated muscular fibre in some vertebrates.—On the development and the morphology of the kidney of osseous fish, by C. Emery.—On the substance preventing the coagulation of the blood and lymph whilst these contain peptone, by Jules Fano.—On the germs and lower

organisms found in ordinary and malariac earths, by A. Ceci.—Transfusion of blood and its effects on nutrition, by P. Albertoni.—On the pathological anatomy of the cornea in the glaucomatous eye, by F. Tartuferi.—On the presence of a cordon or slip on the Uncus of the Hippocampus in the brain of man and some other animals, by C. Giacomini.—On the chemical composition of the egg and its envelope in the common frog (*Rana temporaria*), by P. Giacosa.—Anatomical considerations of the doctrine of cerebral localisations, by C. Golgi.

Tome ii. fasc. 3, February 1, 1883, contains anatomical considerations of the doctrine of cerebral localisations, by C. Golgi (continued).—On compensative hypertrophy of the kidney, by C. Golgi.—Experimental studies on hypnotism, by A. Tamburini and G. Seppili.—The origin of the mesoderm and its relations to the vitellus, by G. Romiti.—On the anatomy of a fœtal Otaria (*O. jubata*), by L. Camerano.—On the physiology of smooth muscular tissue, by A. Capparelli.—On the physiological action of certain substances on the vesical muscles, by P. Pellacani.—On the anemia of miners from a parasitological point of view, by E. Perroncito.—On the change in form of uric acid by the action of glycerine, by J. Colasanti.—On Ptomaines, by J. Guareschi and A. Mosso.—On some endoparasitic Protista, by Dr. Grassi.

Tome iii. fasc. i., April 15, 1883, contains:—On the sanitary improvement of the Roman Campagna, by C. Tommasi-Crudeli.—On the anemia of miners (conclusion), by E. Perroncito.—On some endoparasitic Protista (conclusion), by Dr. Grassi.—On the presence of a secretive tissue in vertebrates, by C. Emery.—On vibratile endothelium in mammals, by J. Paladino.—On the attenuation of charbon virus, and on its transmission from mother to fœtus, by E. Perroncito.—On the acoustic epithelium, by A. Tafani.—On the termination of nerves in the striated muscles of torpedo, by J. V. Ciaccio.—The general physiology of smooth muscular tissue, by E. Sertoli.—On a new morphological element of the blood, and its importance in thrombosis and coagulation, by J. Bizzozero.—New studies of the chestnut disease, known as the ink disease, by J. Gibelli.

THE *Bulletin de l'Académie Royale des Sciences, des Lettres, et des Beaux-Arts* for 1883, part i., contains papers by F. Henrijean, on the part played by alcohol in nutrition; by MM. Valerius and Van der Mensbrugghe, on M. Delaurier's observations on the concentration of solar rays and the transformation of electricity into heat; by W. Spring, on the colour of marine, lacustrine, and fluvial waters; by C. Le Paige, on the homography of the third order in algebra; by Baron Northomb, on the political relations of the Netherlands during the seventeenth century.

SOCIETIES AND ACADEMIES

LONDON

Royal Society, February 1.—"On the Affinities of Thylacoleo." By Prof. Owen, C.B., F.R.S., &c.

Since the communication of the paper "On Thylacoleo," in the *Philosophical Transactions* for 1871, further explorations of the caves and breccia-fissures in Wellington Valley, New South Wales, have been made, by a grant for that purpose from the Legislature of the Colony, and carried out by E. B. Ramsay, F.L.S., Curator of the Museum of Natural History, Sydney. The present paper treats of the fossils contributing to the further restoration of the great carnivorous Marsupial (*Thylacoleo carnifex*, Ow.) They exemplify the entire dentition *in situ* of the upper and lower jaws of a mature individual; the bones of the forelimb, of which those of the antibrachium and the ungual phalanges are described, are compared with those of other Marsupials, and of placental, especially feline, *Carnivora*. An entire lower jaw with the articular condyles adds to the grounds for determination of the habits and affinities of the extinct Marsupial.

Figures of these fossils of the natural size accompany the paper.

Geological Society, May 9.—J. W. Hulke, F.R.S., president, in the chair.—Rev. William Spiers and H. A. Williams were elected Fellows of the Society.—The following communications were read:—The age of the newer gneissic rocks of the Northern Highlands, by Mr. C. Callaway, D.Sc., F.G.S., with notes on the lithology of the specimens collected, by Prof. T. G. Bonney, F.R.S. The object of the author was to prove that the eastern gneiss of the Northern Highlands, usually regarded as of "Lower Silurian" age, was to be placed in the Archæan. While admitting that this gneiss frequently overlies the quartzo-dolomitic group of Erriboll and Assynt, he held that this relation was due to dislocation accompanied by powerful thrust from the east, which had squeezed both formations into a series of folds, thrown over towards the west, so as to cause a general easterly dip. In Assynt the "Upper Quartzite" was first discussed. The author described several sections which he considered to prove that this band was the ordinary quartzite repeated east of a great fault, which brought up the Hebridean; in one place, Glen Coul, the quartzite being conformably succeeded by the brown flags and dolomite. The "igneous rocks" of Nicol ("Logan Rock" of Dr. Heddle) were regarded as the old gneiss brought up by a fault and thrown over on to the Assynt group to the maximum breadth of more than a mile. The "Upper Limestone" of authors was described as either outliers of the dolomite or a part of the Caledonian series. The "Caledonian" rocks were seen in Glen Coul to be immediately overlying the Hebridean, the Assynt group being caught in the angle between the two gneisses, and bent back in overthrown folds. The mountain groups of Assynt were described as usually consisting of cores of Hebridean gneiss swathed in or capped by sheets of quartzite. In the former case the quartzite on the western slopes was contorted into overthrown folds by the thrust from the east. In the Loch Erriboll district, the "granulite" of Nicol was considered to be a lower division of the Caledonian gneiss, though bearing some resemblances to the Hebridean. In other respects the views of Nicol were regarded as substantially correct. Along the entire length of Loch Erriboll, a distance of about twelve miles, the thrust from the east had bent back the Assynt group into overthrown folds, and pushed the Caledonian gneiss on the top of the inverted quartzite. This had produced the appearance of an "upper" quartzite passing "conformably" below the eastern gneiss. The superior antiquity of the Caledonian was confirmed by the occurrence of outliers of quartzite upon the Arnaboll (Lower Caledonian) series, and by the fact that the granite, which sent numberless veins into the gneiss, never penetrated the quartzite and associated rocks.—On a group of minerals from Lilleshall, Salop, by C. J. Woodward, B.Sc., F.G.S.—Fossil Chilostomatous Bryozoa from Muddy Creek, Victoria, by A. W. Waters, F.G.S.

Chemical Society, May 17.—Dr. W. H. Perkin, president, in the chair.—Capt. W. de W. Abney, F.R.S., delivered a lecture on photographic action studied spectroscopically. The lecturer said he wished that all chemists were photographers; photography occupied the borderland between chemistry and physics; he was firmly convinced that photographic action was interatomic. The action of a developer was then experimentally illustrated; this action is physical. Light causes the liberation of iodine in a film of silver iodide, and the developer precipitates metallic silver. The silver so reduced is infinitesimal, and must be in many cases derived from the film. The positive pole of the electric arc was found to be the best source of light. Gratings could not be used for quantitative work, as they varied so much in their ruling; a glass prism was therefore used to form the spectrum. A film of silver chloride absorbs only the violet end of the spectrum; silver iodide absorbs more, and the bromide most of all; accordingly when a photograph of the spectrum was taken on these three films it was seen that the portion of the chloride acted upon was very much less than when bromide of silver was used. It was shown that a sensitiser essentially takes up the halogen liberated by the action of light. One salt of silver may act as a sensitiser to another salt of silver. Photographic action is completely prevented by the presence of oxidisers, as bichromate, &c. Reverse photographs were discussed, and the action of sodium sulphite in preventing the evil effects of over exposure. The peculiar green condition of silver bromide which is sensitive to ultra-red rays was explained. In conclusion the lecturer said that his principal object was to warn chemists of some of the numerous pitfalls which they might encounter in scientific photography.

Meteorological Society, May 16.—Mr. J. K. Laughton, F.R.A.S., president, in the chair.—F. A. Bellamy, T. A. Mercer, Rev. H. J. Poole, and A. Wise, M.D., were elected Fellows of the Society. The following papers were read:—Composite portraiture adapted to the reduction of meteorological and other similar observations, by G. M. Whipple, B.Sc., F.R.A.S. It has often been remarked that one of the main, if

not the chief, of the difficulties the meteorologist has to contend with, is the enormous amount of preliminary labour which has to be expended in the not very pleasing task of forming the observations he may wish to discuss into tables, casting the columns of figures so obtained, and then computing the means. With the view of arriving at results by a shorter cut, the author has been led to consider the possibility of employing a method, suggested by a consideration of the highly ingenious system of composite portraiture, invented by Mr. Francis Galton, F.R.S., and utilised in his anthropological studies.—Note on atmospheric pressure during the fall of rain, by H. Sowerby Wallis, F.M.S. The author discusses the condition of atmospheric pressure while rain was falling, during 1882, and finds that, out of a total of 136 rainy days (which were available for his purpose), on 54 per cent. the rain was accompanied by diminishing pressure, on 27 per cent. by increasing pressure, and on 19 per cent. by steady pressure.—New method of reading a thermometer and hygrometer at a distance by means of electricity, by Arthur W. Waters, F.G.S.—An integrating anemometer, by W. F. Stanley, F.M.S.—Observations on the force of the wind at sea, by D.W. Barker, F.M.S.—Meteorological observations at Zanzibar, east coast of Africa, during 1880 and 1881, by Surgeon-Major C. T. Peters, M.B.—Diurnal rainfall at Bangkok, Siam, by Capt. G. H. Inskip, F.R.G.S.

BERLIN

Physiological Society, April 27.—Dr. Mendel read a paper on the anatomy of the corpus striatum and lenticular nucleus. The older view, which was supported by the valuable anatomical researches of Prof. Meynert, was that the relation of the corona of radiating fibres above the lateral ventricle ("Stabkranz") to the lenticular nucleus and corpus striatum consisted in this, that in it ran bundles of nerve-fibres, which arise from the brain cortex and end in the large ganglia, whereas Dr. Wernicke three years ago propounded the view that a connection did not exist between the brain cortex and the corpus striatum and lenticular nucleus, but that these latter were bodies of the same range as the cortex. Dr. Mendel has for some years past studied the anatomy of these parts of the brain very attentively, and has been brought back to the older view by a series of sections (of the brain) of dogs, monkeys, and men, which series he laid before the Society. He found not only the bundles of out-streaming fibres, which alone were acknowledged to exist by Dr. Wernicke, but also a larger number of in-streaming bundles of fibres which show the connection of these brain-nuclei to the cortex. In the discussion Dr. Wernicke stated that he was not convinced by the paper or preparations of the correctness of the view propounded by Dr. Mendel, whereas Prof. Munk believed that his not-yet-completed physiological experiments afford grounds for Dr. Mendel's view.

Physical Society, May 4.—Prof. Hauck laid before the Society a model of a mechanical apparatus which solves the problem of combining drawings and photograms, which are drawn in two planes into a combination figure in the third plane. Prof. Hauck then explained the principle of the apparatus, and pointed out by means of geometrical figures the conditions which must be fulfilled in order to project any given points of two planes in common points of a third plane. He then proceeded to the complicated problem of bringing points of three planes, which meet in a corner, to a common projection, and applied these figures to the special case of projecting the perspective drawing of a building from its ground-plan and elevation. The model was calculated and arranged for this case, but the apparatus, in which the motions are produced by means of polished lineals, each running upon two pins, can be put to manifold uses in physical space investigations.

PARIS

Academy of Sciences, May 14.—M. Blanchard, president, in the chair.—The following papers were read:—On the pyro-electricity of quartz, by C. Friedel and J. Curie, second part.—On the cultivation of the cacao plant, with an analysis of the constituent elements of the cacao and chocolate berries, which were shown to contain in various proportions albumen, legumine, phosphates, fat, starch, sugar, theobromine, besides the materials entering into the formation of bone.—On the action of birds in flight studied by means of photography, with figures showing the successive positions of a pigeon on the wing at intervals of one-ninth and one-eighth of a second, and a closed curve representing the trajectory of the tip of the wing obtained by means of a special contrivance, by M. Marey.—On a double sulphate of iridium and potassium, by M. Lecoq de Boisbaudran.—On the diminution of virulence in carbon bacterides and their spores under the influence of antiseptic substances, by MM. Chamberland and Roux.—On iodine associated with the sedative alkaloids of opium treated both as a preventative and curative in the case of typhoid fever, by A. Delbovier.—On the immunity against attacks of Phylloxera enjoyed by the vine cultivated in the sandy soil of Algeria, by MM. F. Convert and L. Degrully.—Observations on the new planet 233 Borelly made at the Paris Observatory, by G. Bigourdan.—On the determination of the meridian in low latitudes, such as that of Rio de Janeiro, by M. Cruls.—On the conservation of energy and periodicity of the solar spots, by A. Duponchel.—On the laws of coincidences between the reductions of periodical fractions of the "two modes," by E. de Jonquières (continued).—On the generalisation of Thermat's theorem of numbers due to M. Serret, by M. Picquet.—On the possibility of extending to any electrolytic field the electro-chemical method in the figuration of potential distribution, by A. Guébhard.—On the influence of atmospheric pressure on the eruptions of gas and water in the Montrond Geyser (Loire), by F. Laur.—On the differences in the temperature of the sea and air, by M. Semmola.—On the quantitative analysis of sulphur and carbon in sulphocarbonates, by A. Müntz.—On the regular surface-fissures in certain rocks, such as the hard eocene limestone used in the construction of the old ramparts of Genoa, by Ch. Contejean.—On new physiological studies of the torpedo, by M. Marey.—On the functions and organs of suction and deglutition in the leech, by G. Carlet.—On a case of purulent ophthalmia produced by the infusion of the seeds of the liquorice plant, by L. de Wecker.—On the fundamental principle of the electric log now in use in the French fleet, by M. G. Le Goarant de Tromelin, who claims priority of invention over the electric log invented by M. Fleuriais.

WIEDEMANN'S "ELECTRICITY"

Die Lehre von der Electricität. Von Gustav Wiedemann. Vol. I., pp. xi. and 795 (1882); Vol. II., pp. vii. and 1002 (1883). (Braunschweig: Vieweg.)

FOR more than twenty years Prof. Wiedemann's "Lehre vom Galvanismus und Elektromagnetismus," first published in 1861, has been recognised without question as the leading authority and great storehouse of facts on the branch of science of which it treats. It is a practically exhaustive treatise, and each of the two editions (second edition, 1872 to 1874) marks with wonderful accuracy the high-water mark of knowledge of its subject up to the date of publication. It is safe to assume that any fact that is not to be found recorded in its pages had not been discovered, or at least had not been published, up to the date of completion of whichever edition is examined. The fulness and accuracy of the references to original authorities give to Prof. Wiedemann's book a unique value also as a classified index to the literature of galvanic electricity and electromagnetism.

The work which forms the subject of this notice, is in one sense a third edition of the "Lehre vom Galvanismus." It appears however under a new title, and is in fact to a great extent a new book. It is characteristic of the direction taken by the advance of electrical science during the last twenty years that, while Prof. Wiedemann found it practicable to confine himself in his first and second editions almost exclusively to the phenomena of current electricity and of magnetism, he has found it advisable in the present edition to enlarge the scope of his work so as to make it include the whole range of electrical science. It is true that the second edition contains an important chapter devoted to the discussion of a phenomenon that has usually been considered in connection with statical electricity, namely, the disruptive discharge in gases of different densities; but this is almost the only part of the book in which the considerations that have to be dealt with in treating of electrostatics occupy a prominent place. It is however becoming less and less possible to treat satisfactorily of one branch of electricity apart from the remainder. The terms frictional electricity and galvanic electricity have evidently an historical rather than a scientific origin. They do not refer to any logical classification of phenomena, but to two among the many processes by which electrical effects can be originated. It is not even by any means certain that electrification by friction is fundamentally a distinct phenomenon from electrification by contact as this occurs in a galvanic cell; on the contrary, various recent investigations tend to show that these actions are essentially similar, and that the friction which takes place in one case is of the nature of an accidental accompaniment. As a matter of fact, however, an electrical machine acting by friction serves (or at least did so until recently) as the readiest means of producing one large class of electrical phenomena; while a galvanic or voltaic battery serves (or at least did so until recently) as the readiest means of producing another large class of phenomena. Thus the division of electrical science for the purposes of study into frictional electricity and galvanic electricity originated in considerations of experimental convenience rather than in any strictly scientific distinction. So far as such a distinction can be drawn between these two branches, it may be said that the former includes the study of all those phenomena in which difference of potentials is the most characteristic factor; while the latter includes the study of phenomena characterised by the transfer of electricity. As examined by the instruments in use five-and-twenty years ago, the effects produced by the electrical machine seemed distinct enough from those due to the galvanic battery—indeed the difficulty rather was to establish their mutual connections; but with the galvanometers and electrometers that are now—thanks to Sir William Thomson—in the hands of every electrician, nothing is easier than to measure the current of an electrical machine or the difference of potentials of a galvanic cell. Moreover the recent rapid development of methods of converting mechanical into electrical energy, through the agency of magneto-electric induction, has made us familiar with the production of currents of great strength associated with great differences of potential. It is, however, not only the introduction of new instruments and apparatus, and the increased power over electrical phenomena that modern experimentalists have thereby acquired, that make it less possible now than formerly to treat of the laws of electric currents without reference to the principles of electrostatics. The conception that the immediate cause of the phenomena exhibited in either an electric or a magnetic field has its seat, not in electrified conductors, or in magnets or conducting wires, but in an impalpable medium existing throughout space, has completely shifted the scientific point of view as regards electrical effects. What is now demanded of electrical theory is an explanation of the conditions of the medium which are perceptible by us as the properties of an electric or magnetic field. The wider problem of the constitution of the electric medium, whether identical or not with the luminiferous ether, embraces in itself the phenomena of electrostatics, of electric currents, and of magnetism

There was thus every reason to wish that Prof. Wiedemann might be able to treat electrical science as a whole in the same complete way in which he had previously treated the portions included within the scope of his previous book. This is what he has now undertaken and in great part accomplished. The task is an enormous one, and probably, to any one except the man who has set himself to it, would have seemed overwhelming. Prof. Wiedemann's industry and care, however, never seem to fail before any mass of descriptive detail or complex mathematical discussion, and students of physics may therefore be congratulated upon the near prospect of having from his pen a complete treatise on electricity.

The first of the two volumes already published begins with a section on the General Properties of Electricity, including an historical sketch of early observations, the development of electricity by friction, &c., electrostatic attraction and repulsion, distribution on conductors, and a description of the various forms of electroscopes and electrometers. Then follows a section on the development of electricity by contact of heterogeneous bodies; next Ohm's law and its applications, the measurement of electrical resistance and of electromotive force, and a

description of various galvanic elements. These subjects occupy the first volume, consisting of close on 800 pages. The second volume begins with the electrical properties of dielectrics. The section devoted to this subject is erhaps the most interesting in the volume: it contains the mathematical theory of the behaviour of dielectrics, the experimental investigation of specific inductive capacity, the detailed study of electrical machines acting by friction and by induction, together with various allied matters. Next come thermoelectricity, pyroelectricity, and the thermal effects of the discharge of accumulated electricity and of continuous electric currents. After this follows the section devoted to electrochemical action: this occupies about five hundred pages, and concludes with a chapter on the theory of electrification by contact, which completes the volume. It is intended that the whole work should be finished in four volumes, and the manuscript of the two that still remain to be published is for the most part ready.

Prof. Wiedemann's great work has been so long known to physicists that it is needless for us to dwell upon its special qualities farther than to say that it fully retains in its new form all its old characteristics. It is true that it lacks the originality and unity of treatment of Clerk Maxwell's "Electricity and Magnetism," probably the most original systematic treatise on any great branch of physics that was ever written. Nor does it equal in the clearness and elegance of its mathematical discussions the treatise of Mascart and Joubert, a work which, while not laying claim to originality in respect of matter, exhibits in a remarkable degree consecutiveness and lucidity of exposition. Prof. Wiedemann's plan precludes his attaining to these particular excellences in an equal degree. Some sacrifice of unity and consecutiveness is inevitable in a work which aims not only at giving a complete account of what is known respecting a great branch of science, but also at showing what each author has contributed to the stock of knowledge and how he has presented it. From this point of view Prof. Wiedemann's book is without a rival in any language, and is indeed unapproached by any other work. G. C. F.

FLORA OF HAMPSHIRE

Flora of Hampshire, including the Isle of Wight, or a List of the Flowering Plants and Ferns found in the County of Southampton, with Localities of the Less Common Species. By Frederick Townsend, M.A., F.L.S., &c. Illustrated with Two Plates and a Map. (London: L. Reeve and Co., 1883.)

WE have here an important addition to the already large class of English local floras. To the general botanist, as to people who have made no study of botany, it would seem that the plants of so comparatively small a region as the British Islands must have been catalogued long since, and that there is little to be done in that direction which is worth doing. It certainly is remarkable that, besides facts connected with geographical distribution, which a more minute knowledge of the plants of a country must bring to light, there are actually new plants to be found—new, that is to say, not only to Britain, but to science. A Pondweed (*Potamogeton Griffithii*), new to science, has recently been described and figured by Mr. Arthur Bennett in the *Journal of Botany*, from specimens brought from a mountain lake in North Wales—the only place in the world where it is known to occur. Not that this is the only species peculiar to these islands. To take one example, there is a species of Centaury (*Erythræa latifolia*),[1] which has never been found anywhere in the world but on the Lancastrian sandhills; and there it is not known to have been seen more recently than 1865, if then. In Mr. Townsend's county, a Spearwort (*Ranunculus ophioglossifolius*), not hitherto found nearer these shores than Jersey, has been detected so lately as to appear only on the very last page of the book; *Spartina Townsendi* is another case in point; and another example of a plant having been long overlooked, and of which the distribution has quite recently been much extended, will be found in *Arum italicum*, which was detected in the Isle of Wight in 1854, and was afterwards found in West Cornwall and Sussex; this was recorded for Dorset last year, and its range has been extended during the present year to Kent (Folkestone). The volume now before us supplies a good illustration of the way in which novelties may turn up in the best known districts. Probably if there is one part of England which has been more thoroughly botanised than another it is the Isle of Wight; yet it was here, and in one of the best known parts—the Downs at Freshwater—that Mr. Townsend first distinguished in 1879 an *Erythræa* (*E. capitata*, var. *sphærocephala*), which is, as he says, "a peculiarly interesting addition to the British flora. It is," he continues, "a well-marked species, and is not known now to occur anywhere else in the world but in the Isle of Wight and in Sussex. The other form of it was found some fifty years ago somewhere in the neighbourhood of Berlin (the exact locality not being known), and though sought for diligently, it has never been found again."

It will doubtless seem strange to some to learn that a volume of more than 500 closely-printed pages can be occupied by an enumeration of the plants of one English county, especially when it is considered that the pages devoted to descriptions of species are very few. An interesting and instructive article might be written in which the history and development of the local flora should be traced. To undertake such is, however, not our present purpose; but we may note one or two of the more striking features of these later contributions to local botany, of which the "Flora of Hampshire" is the most recent. One thing to be noticed is their historical nature. Messrs. Trimen and Dyer, in their "Flora of Middlesex" (1869), were the first to develop this aspect of the work: their method of quoting the first authority for the occurrence of the species as a Middlesex plant has been followed by subsequent writers, and they also did good service by quoting the synonymy of the older (and pre-Linnean) authors—a work which has been very useful to their successors. When it is considered that a book of this kind is mainly undertaken by persons interested in the history of some particular locality, it seems natural that what has been called the antiquarian side of botany should be represented, although there are those who consider that

[1] The plant so named in Continental floras is certainly not the same as that of the Lancashire sandhills.

this line of action directs attention to persons rather than plants, and is thus out of place.

Another point to which much more attention is given now than was formerly the case is the division of a county into districts. Messrs. Webb and Coleman, in the "Flora Hertfordiensis" (1849), planned their divisions with reference to the river drainage; and this has been carried out in the best floras of later times. If it were generally adopted, and if our list of county floras were complete, we should arrive at a much greater knowledge of plant distribution than we have at present. The arbitrary boundaries of counties would give way to the natural divisions afforded by the various river-basins, and one county flora would fit into another, and form a harmonious whole. This subject has lately been worked out by Mr. Boulger in a careful paper "On the Origin and Distribution of the British Flora," published in the *Transactions of the Essex Field Club*. No one who has not tried it would suspect how greatly the floras of contiguous river-basins will be found to differ from each other.

It is time, however, to speak of Mr. Townsend's important contribution to our knowledge of local botany. As is well known, the work has occupied him during a large number of years: it has, we regret to say, been retarded by the ill-health of its author, or it would have been published two years since; but Mr. Townsend tells us that the delay has enabled him to improve the book in various details. The county is divided into twelve districts, two of which are in the Isle of Wight. A small but extremely clear and useful map showing the boundaries of these is given. The usual lists of books quoted and herbaria consulted are followed by a short sketch of the plan of the flora. The distribution of each species through the districts and subdistricts is then worked out at length. We confess to feeling some disappointment at the comparative fewness of the critical notes upon species. Mr. Townsend's extensive knowledge of British plants, especially in their relations to the Continental flora, had led us to expect that we should have had a good deal of additional light thrown upon some of our critical forms; but this, although not altogether wanting, occupies but a small portion of the volume. Mr. Townsend's notes are for the most part in the appendix—an arrangement which seems to us open to various objections, not the least being the fact that these notes and descriptions are often not mentioned in the index. Two or three varieties are described and named for the first time in these pages; and occasionally a specific name new to the British flora makes its appearance, as in the case of *Glyceria declinata* of Brébisson, with which Mr. Townsend identifies a plant which he had previously considered a dwarf variety of *G. plicata*.

One or two points seem to us open to criticism. "First record" in books of this kind is usually taken to mean first record in print; but this is not Mr. Townsend's view of the phrase. Thus under *Centaurea cyanus* we find, "First record: Herb. Reeves, 1837." It does not seem to us that the existence of a specimen in a private herbarium can be considered a record of its occurrence in the ordinary acceptation of the term. Sometimes we do not quite understand the author's meaning, as when he marks the curious and interesting *Spartina Townsendi* as "certainly introduced," although it has as yet been found nowhere else in the world. Equally puzzling is this sentence as to the specific rank of the same grass: "I believe this plant must take the rank of a sub-species; the characters which separate it from *S. stricta* being so important and distinctly marked. It is easily distinguished from *S. alterniflora*." This being so, surely it should be ranked as a full species? Mr. Townsend admits *Anthoxanthum Puelii* as indigenous, but its frequent substitution for *A. odoratum* by seed merchants throws much doubt upon its nativity: this plant, first found in Hampshire in 1874, had been collected in Cheshire two years previously, but Mr. Townsend cites the last-named county as one of those in which it "has since been found." We can, from observation of the two plants in several counties, confirm the statement of Mr. Pryor, which is doubted by Mr. Townsend, that *Viola Reichenbachiana* flowers about a fortnight earlier than the allied *V. Riviniana*. Some plants are included as natives of Hampshire on what seems to us insufficient evidence; *Silene noctiflora* is one of these, and *Orchis hircina* another. This latter, we do not hesitate to say, requires much confirmatory evidence before it can be accepted as a Hants plant; its occurrence rests solely on a manuscript note of the late Mr. Reeks, who stated that specimens had been found by a Mr. Lockart at St. Mary Bourne about 1866. The number of misprints is very considerable.

Such criticisms as these—and they might easily be extended—do not, however, prevent the "Flora of Hampshire" from taking a foremost rank among works of its class. A little more attention to uniformity would have improved the book, and, as we have shown, there is room for difference of opinion upon many of the points raised; but British botanists will be grateful to Mr. Townsend for giving them a handbook to the flora of one of the most interesting and beautiful of our English counties.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*

[*The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to insure the appearance even of communications containing interesting and novel facts.*]

On Real and Pseudo-Reversals of Metallic Lines

I AM much indebted to the courtesy of Prof. Liveing for a copy of a paper extracted from the *Proceedings of the Cambridge Philosophical Society*, vol. iv. part 5, p. 256, on the circumstances producing the reversal of spectral lines of metals, by Professors Liveing and Dewar. In this communication the following paragraph occurs:—"Prof. Hartley has lately (*Proc. Roy. Soc.* xxxiv. p. 84) called attention to pseudo-reversals of this class, which may be produced in the case of a strong line by over-exposure. It is well known that over-exposure (solarisation, as we used to call it formerly) produces such an alteration in the sensitive preparation of the photographic plate that the over-exposed parts cease to be developable, so that a very strong line may appear white in the negative where it ought to be black, but with a dark border, and so give the appearance of a reversed line. Prof. Hartley finds it difficult to distinguish real reversals of the class we are now discussing from these pseudo-reversals. His difficulty has not occurred to us, first, because we have always been in the habit of taking photographs in series with varying exposure, in order to get impressions both of the feeble lines in some and of strong lines in others; and

secondly, because we almost always close part of the slit of the spectroscope with a shutter, so that the image is cut off sharply by the shadow of the shutter. Strong lines extend into the shadow more or less, and if there is a real reversal the extension of the reversed part into the shadow is trumpet shaped, whereas if it is only a pseudo-reversal it is closed."

I beg to be allowed to call attention to one or two points in the above quotation which I imagine may lead to a misconception of the phenomena observed, and of my remarks thereon.

First, as regards over-exposure, it is assumed that solarisation is an equivalent for this expression. This is the case only when speaking of the cause, but the word has been used by photographers for many years to describe the effect of over-exposure.

In all collodion processes, wet or dry, this effect is an undue intensity of the high lights and an overpowering of the intermediate tints and delicate shadows adjoining them. This appears to be due to the fact that from the intensity of the light not only the direct rays, but those reflected from the back of the glass plate, or even those which are scattered, have sufficient power to act upon the sensitive film. In photographs of spectra this is seen in the nimbus or halo surrounding the strongest metallic lines, which disguises their form. It is well illustrated by my photographs of the magnesium, cadmium, and other spectra, published in the *Journal of the Chemical Society*, vol. xli., *Transactions*, 1882, p. 90.

Although I have worked with dry plates of almost every description, and with some modifications prepared by myself which have never been described, I do not recollect having observed that over-exposure causes any other effect than a too dense deposit of silver, excepting when the vehicle for the sensitive salt is a film of gelatine. As far as my experience goes, it is a property peculiar to gelatine plates, that with such extreme facility they are incapable of development after too strong an action of light, and I carefully avoided the term solarisation, since it has been used to describe an effect so different from that to which I desired to call attention.

Secondly, with regard to difficulty in distinguishing reversals, the sentence above does not exactly represent my experience, and I think it may be seen by those who read my communication, that any want of distinction between real and pseudo-reversals had reference only to photographs which had been already taken with a fixed period of exposure, and that I advocated a method of comparative exposures as necessary in the study of spectra. It appears that this is one of the means whereby Professors Liveing and Dewar are able to draw distinctions between real and pseudo-reversals. The second method, namely, the use of a shutter, is extremely useful in observations on arc spectra, which have been so completely studied by them. I have been studying spark-spectra exclusively, and have not been giving special attention to reversals, in fact, endeavouring as far as possible to avoid them. The use of a shutter does not commend itself to me, since it would cut off a highly characteristic feature in spark-spectra which it is desirable to observe, namely, the extension of the lines, but I may here mention that a speck of dust on the slit, or a fine wire stretched across it, will answer the same purpose as a shutter, without obscuring any considerable portion of the spark, and may be conveniently employed. And now permit me to add one word: the same alteration in the intensity of the spark which results in real reversals also frequently causes pseudo-reversals. Sometimes simply a turn of the screw attached to the spring of the contact-breaker on the induction-coil is sufficient to effect this change.

W. N. HARTLEY

Royal College of Science, Dublin, May 18

The Northern Zoogeographical Regions

THE facts of zoogeography are so involved, and often apparently contradictory, that a skilful dialectician with the requisite knowledge can make a plausible argument for antithetical postulates. Prof. Heilprin, being a skilful dialectician and well informed, has submitted a pretty argument in favour of the union of the North American or "Nearctic" and Eurasiatic or "Palæarctic" regions (*Proc. Acad. Nat. Sc. Phila.*, 1882, pp. 316–334, and NATURE, vol. xxvii. p. 606), but Mr. Wallace has, with perfect justness it seems to me, objected to his proposition (NATURE, vol. xxvii. pp. 482, 483). As Prof. Heilprin's arguments have not been entirely met, however, permit me to submit some further objections to his views.

Prof. Heilprin has contended "(1) that by family, generic, and specific characters, as far as the Mammalia are concerned, the Nearctic and Palæarctic faunas taken collectively are more clearly defined from any or all of the other regions than either the Nearctic or Palæarctic taken individually; and (2) that by the community of family, generic, and specific characters the Nearctic region is indisputably united to the Palæarctic, of which it forms a lateral extension."

Prof. Heilprin has formulated these conclusions after a summary of the families and genera common and peculiar to the regions in question.

As to families, Prof. Heilprin has presented the following figures:—

	All.	Peculiar.
Nearctic	26	1
Palæarctic	36	0
Oriental	36	3
Australian	22	8
Ethiopian	44	9
Neotropical	31	8

The proportions of peculiar genera to the entire Mammalian faunas of the several regions are stated to be as follows:—

	All.	Peculiar.	Percentage.
Nearctic	74	26	35
Palæarctic	100	35	35
Oriental	118	54	46
Australian	70	45	64
Ethiopian	142	90	63
Neotropical	131	103	78

The question may naturally recur why the line which separates "regions" from "subregions" should be drawn between 35 and 46 per cent. rather than between 46 and 63 or 64 per cent., or even between 64 and 78 per cent. Prof. Heilprin has not told us why, and I am unable to appreciate the reason therefor. Surely it is not sufficient to answer by simply asking the questions put in NATURE (p. 606).

But an analysis of more (but only approximately) correct figures and a more logical classification of mammals than that adopted by Prof. Heilprin reveal facts materially contravening the tabular statements of that gentleman.

First we must exclude the marine mammals, because their distribution and limitation are determined by other factors than those which regulate the terrestrial ones. A consideration then of the terrestrial forms leads to the following results:—

The Arctamerican or Nearctic region has 27 families, of which 11 are not shared with Eurasia and 4 are peculiar; it has 68 genera, of which 45 do not enter into Eurasia.

The Eurasiatic or Palæarctic region has 32[1] families, of which 17 are excluded from North America, and it possesses 89[1] genera, of which 60 have failed to become developed in America.

Such contrasts will more than compare generally with those existing between Eurasia and India, and even between the "Triarctic" or "Holarctic" and Indian "regions," and the same destructive process by which the northern regions are abrogated would entail the absorption of the Indian as well into a heterogeneous whole. The three can in fact be well united (as Cænogæa), and contrasted with a group (Eogæa) consisting of the African, South American, and Australian regions, as I long ago urged (*Ann. and Mag. Nat. Hist.* (4), xv. 251–255, 1875), but the claims of each to be considered as "regions" or realms is not thereby affected.

THEO. GILL

Smithsonian Institution, Washington, May 12

Deductive Biology

THOUGH no writer has yet afforded any remarks in criticism of Prof. Thiselton Dyer's "word of warning" to biologists, given in NATURE, vol. xxvii. p. 554, it does not, I think, follow that the objection raised by him is to be accepted as unanswerable. As no one of authority in such matters appears to be forthcoming, perhaps one who can lay no claim to being heard may still be permitted to venture to doubt the validity of the objection as given forth in such emphatic terms by Prof. Dyer, and to point out that most, if not all, of the scientific conclusions of importance, especially those accomplished during the present generation, have been arrived at mainly by means of the deductive method.

[1] These are the groups admitted by Prof. Heilprin, exclusive of the Pinnipeds.

The objection started is a serious one, for, if the deductive method is wrong at all, it is so absolutely, and must on no occasion be allowed a place in scientific reasoning, but—without any half-measure allowances—must be excluded altogether as a false and dangerous element of philosophy. If, on the other hand, we take exception, as I think we may do, to the exponent's opening expression,—"having formulated a few fundamental assumptions, to spin out from these explanations of what we see in the world about us . . . is merely a literary performance,"—as misleading in its main idea, we may still hold the method to be a perfectly scientific one.

The evolutionist, who has once ascertained by various careful experiments and extensive researches that there is a direct natural sequence of events in connection with certain phenomena, may be allowed to adopt set principles as recognised laws of action, fully as much as Euclid in the demonstration of problems from his formulated axioms. But perhaps Prof. Dyer's argument rests in reality upon his use of the word "assumptions," and thus his objection is merely urged against the false method assumed in his premise, rather than against deductive biology as a method of procedure, as he would have us believe. And so far, of course, every one will readily enough accept Prof. Dyer's remark as it stands.

But the conclusion that "the deductive method is a bad way of solving morphological problems" is opposed to all the evidence of Darwin himself, who constantly applied those well-tested principles which he had discovered even by this very method, and upon the bases of such fundamental *truths* it was that he reared his wonderful system. Are not the studies of comparative embryology and osteology, of comparative histology and biology, each founded entirely upon the method of deductive analogy?

As another sufficient witness, Mr. Wallace may be quoted as having adopted the same course with such remarkable results, and throughout his writings bears testimony to the value of deductive inference as a method of procedure, and I will deduce a couple of sentences taken from his work on "Island Life," bearing directly upon our point.

"On the theory of evolution," he says, "nothing can be more certain than that groups now broken up and detached were once continuous, and the fragmentary groups and isolated forms are but the relics of once widespread types which have been preserved in a few localities where physical conditions were especially favourable, or where organic competition was less severe. The true explanation of all such remote geographical affinities is that they date back to a time when the ancestral group of which they are the common descendants had a wider or a different distribution," &c., p. 296. And, in summary of the chapters on Madagascar, Mr. Wallace remarks: "The method we have followed in these investigations is to accept the results of geological and palæontological science, and the ascertained fact as to the powers of dispersal of the various animal groups; to take full account of the laws of evolution as affecting distribution, and of the various ocean depths as implying recent or remote union of islands with their adjacent continents; and the result is that wherever we possess a sufficient knowledge of various classes of evidence we find it possible to give a connected and intelligible explanation of all the most striking peculiarities of the organic world" ("Island Life," p. 419). We may then assuredly decide that the deductive system of logic,—the use without abuse of certain known factors,—instead of being in any way "bad," is (granting always that the general laws of Nature applied are sufficiently trustworthy) found to be even superior to the older and tardier processes of induction, to which the mere collectors of the facts dealt with have limited themselves, and has proved itself to be the *only* means of elucidating many of those abstruse problems, the solution of which has been conducive of such immense gain to the scientific philosophy of our day.

WILLIAM WHITE

Science and Art

As a rule it would be the extreme of absurdity for me to venture an adverse remark on the criticism of an art critic on paintings, yet there is one single exception regarding which I may perhaps be permitted to say a word or two.

In the very interesting critique on some pictures in the Royal Academy, written evidently by a master-hand, there is one picture—No. 764, "a snowstorm" (see NATURE, vol. xxviii. p. 76), not only somewhat severely, but I think unjustly or incorrectly, commented upon, because "there is not a single snowflake to be seen in the first twenty yards."

I have witnessed and been in the midst of many snowstorms in America, and some in Scotland. In a large proportion of these not a snowflake was to be seen, the snow being in very minute particles, so fine as to penetrate all openings in the clothing, however small. Snowstorms of this kind are the most dismal, bitter, and chilling of any.

On looking at Mr. Farquharson's picture, I was struck with its resemblance to a most unpleasant evening and night spent in the hills between the Coppermine River and Great Bear Lake, about 50 miles north of the Arctic circle. It being early winter, the weather was not very cold, but there was a combination of fog, fine snow (no snowflakes), and snowdrifts, which produced one of the most dismal and dreary scenes imaginable.

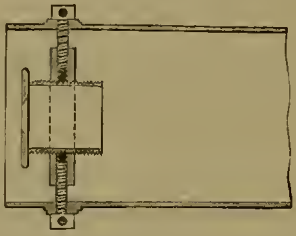
Transit Instrument

IN your issue of the 17th ult. (vol. xxviii. p. 51) you notice a cheap form of transit instrument introduced by me, and you point out the defect that no means are provided for placing the cross wires truly vertical. In all the most recent instruments which have been made this difficulty has been met by an arrangement which answers so effectively that I think it may interest others beyond those who are likely to use the instrument in question.



I employ the ordinary diaphragm with the usual four stretching screws, and the collimation is corrected in the usual manner by these screws. Into this diaphragm I insert a tube with a very fine screw, on the outside of which is fixed a plate carrying the cross hairs; by screwing this tube in or out the focus may be perfectly adjusted for objects at an infinite distance, while a slight additional movement to the right or left enables one at the same time to adjust the cross hairs truly vertical.

LATIMER CLARK

Sea-Shore Alluvion, Dungeness

REVERTING to an article in your journal of July 28, 1881, and a letter of mine in that for April 20, 1882, the following at the present time may be of interest:—

As regards the local wasting away in the bays east and west of Dungeness and the redistribution of the materials at Lighthouse Point;—on the west side the whole margin from Rye Bay to "Denge Marsh Gut," a distance of eight miles, has receded of late years; this is shown by the fact that the Denge Marsh authorities have recently erected a clay counter sea-wall at the back of the modern shingle "fulls" in front of the "Midrips" and "Wicks" (small land-locked pools of water) to check the overflow of the sea in south-west gales. This action is felt to the eastward in front of the "Holmstone," the Lydd coastguard station, and up to "Denge Marsh Gut," eastward of which we have modern "fulls,"—the resultant in part of this waste, overlapping and adding to the south-east outline of the "Ness" or extreme projection of this natural mole of shingle, and thence travelling northward until reaching "Great Stone End," which forms the southern boundary of Romney "Hoy" or Bay, northward of which Dymchurch Wall, an artificial stone-faced sea-wall three to four miles in length, is sufficient evidence of the modern local waste and necessity for sea-defences to the rich grazing district of Romney Marsh. Still further northward the sea-wall recently constructed by the municipal authorities of Hythe is equally suggestive of this recession. Going no further back than Cole's survey of 1617, we have a *status quo ante* very nearly, as regards outline from Rye Bay to within two miles of the lighthouse, and this accompanied by a local south-east increase and movement around the lighthouse,

involving towards the end of the last century the removal of the old and erection of the present tower, which, due to this increase, is now very much in the same relative position as its predecessor of 1792. This local accumulation runs northward to "Romney Hoy," but is accompanied beyond this again northward by a constant struggle to preserve the sea frontage right up to Hythe.

Take the Royal Military Canal, twenty miles long, as the base of a triangle running out ten miles seaward therefrom, with two inclined sides of ten miles and fourteen miles, or twenty-four miles of sea margin in all; of this we have on the west side eight miles of stationary or receding shore, thence two miles to the "Ness," and northward of it four miles, or six miles in all of local increase, and northward again ten miles of stationary or receding shore.

Now under these conditions who is to fix, and on what principle, the landward boundary of what may be termed the "live beach," and is it not this very material (not grass-grown or covered as it ultimately becomes by vegetation) that lies most temptingly for removal?

A very tentative advertisement has recently been displayed at the Charing Cross terminal station of the South-Eastern Railway offering sea-beach or shingle for sale. J. B. REDMAN

Sheet Lightning

SOME people never see lightning; I have met one lady who cannot, and have heard of other instances. The question suggests itself, consequently, whether the duration of a flash of lightning is sufficient to produce a visible image on the retina or whether the image is only produced after successive reflections in the eye itself, which might be too few to produce such an image in the case of people with very dark eyes; if the latter is the case, this would go far towards accounting for the difficulty there is in deciding as to the character of sheet lightning as far as any optical test is concerned, but would indicate the possibility of further light being thrown on the subject by photography.

Ripon, May 24 N. W. TAYLOR

[WE *never* heard of any one (except blind people, of course) who could not see lightning, nor have we any idea how the colour of the iris (or reflection either) can have to do with it. As to the *duration* and visibility of a flash, see NATURE, vol. xxii. pp. 340-41. As to "summer lightning," the following statement from Prof. Tait's lecture on Thunderstorms (NATURE, vol. xxii. p. 438) may be of interest:—"I have said nothing of what is commonly called *summer lightning*, which is probably, at least in a great many cases, merely the faint effect of a distant thunderstorm, but which has also been observed when the sky appeared tolerably clear, and when it was certain that no thunderstorm of the ordinary kind had occurred within a hundred miles. In such cases it is probable that we see the lightning of a storm which is taking place in the upper strata of the atmosphere, at such a height that the thunder is inaudible, partly on account of the distance, partly on account of the fact that it takes its origin in air of small density." We know that Prof. Tait speaks from having himself seen what he here describes, which shows unquestionably that (*on some rare occasions*) its source is really above our heads, and not (as is the general rule) a thunderstorm of the ordinary kind several miles off.—ED.]

Curious Nest-building—"Scarecrows"

THERE is an old house at Whetstone at which a robin lately built its nest in a singular position. The gate in the garden wall, opposite the door, is opened from inside by a servant, when the bell rings. To do this she goes to a little hole in the wall close by the gate, and pushes along a small bell-pull handle in the line of the wall (the motion very slight). In the space behind this handle, and evidently scanty for the purpose, a robin built its nest, and it is now filled with little birds, which stretch out their yellow gaping beaks when one pushes the handle. The case is the more curious in that the master of the house, fearing inconvenience on both sides, had the nest twice removed when in course of building; but the robin persisted, and was ultimately allowed. A little way along from this gate is an old disused pump, the front of which opens on hinges. Round the vertical rod of this pump a tomtit has laboriously built up a pile of twigs and various scraps, quite filling the body of the pump for about a foot in depth; and on the top is the nest proper, with six or seven eggs. The handle is never moved by any one. The bird apparently enters at the hinge.

While on this topic I would ask, Has any systematic study been given to the question of scares for birds? I recently sowed some grass and clover seed on a lawn, and, to scare the sparrows, stuck up some bits of wood, with square pieces of paper, attached with string to flutter in the wind; but from the occasional position of sparrows on the lawn, I suspect the radius of action of these scares was decidedly limited. Are birds most scared by still effigies of persons, or by sight of movements apart from such imitation, or again by sounds, as in a scare I saw lately, where pieces of glass were hung so as to clink together?

Finchley, May 29 M.

Ground Ivy

I SHOULD like to know if a peculiarity I often see in the position of the stigmas in the pistillate form of this flower is generally observed. Instead of the stigmas opening up and down from the style as usual in Labiates, they often diverge to right and left across the flower, and the style also often curves forward, so as greatly to facilitate cross-fertilisation as it seems to me. If I am right this slight change may be of interest as a step towards diœciousness. I found this peculiarity in 291 out of 531 flowers with abortive stamens which I looked at; the stigmas opened in the usual way in 85, while in 141 one stigma was vertical and one horizontal; 14 cases were doubtful. In some unopened buds, the stigmas already diverged horizontally. For comparison I looked at 418 perfect flowers, and here, while the stigmas of 360 opened as usual, only 15 spread horizontally; 34 had one stigma vertical and one horizontal, and 9 cases were doubtful. S. S. DOWSON

Geldeston, May 22

Meteor

I HAVE just seen a very splendid meteor (at 10.40 p.m.). I watched it during about thirty seconds, in which time it traversed the heavens from about the point south-east nearly to that of north-west, where it burst. Its path was nearly parallel to the horizon, probably approaching it at an angle of about 5 degrees. When first seen it appeared nearly yellow as to colour, with a very fine tail, but just before it broke up the colour changed to white, and the fragments reminded me very much of some "magnesium stars" fired from a rocket. No doubt you will have a quantity of communications concerning this meteor. I wondered whether any one else had noticed this appearance.

Filston Hall, Shoreham, Kent, June 3 A. HALL

WASPS (L. C.).—Thanks; but there is nothing new in your observations.

MIMICRY (DR. KESTEVEN).—The occurrence is perfectly well known. It is probably *Urapteryx Sambucana*. You have mistaken the anterior for the posterior extremity.

RECENT ORNITHOLOGICAL WORKS [1]

TO those who imagine that British ornithology is worked out, and that there is nothing left to do in this well-worn field, we commend the study of the present book, as presenting us with a delightfully fresh view of an old and familiar subject. The author is already well known to the public from his admirable books of Siberian travel, but it is only his private friends who have been aware of the devotion to this favourite branch of science which has characterised Mr. Seebohm for many long years, when most people imagined him to be absorbed in business in the north of England. Brief excursions to points of interest on our own coasts, snatched in intervals of scanty leisure, succeeded in after years by more important expeditions to Greece and Asia Minor, the River Petchora, the Yenisei, &c., have given him an acquaintance with field-ornithology which is surpassed by few of his contemporaries, while the fact that the dry details of literary research have no terrors for him is proved by the

[1] "A History of British Birds, with Coloured Illustrations of their Eggs." By Henry Seebohm. Published by the Author, 1883.

masterly way in which he executed the fifth volume of the British Museum "Catalogue of Birds."

The present volume, however, will appeal to a class of readers very different from those who study the high and dry literature above-named, and even those accustomed to the well-written pages of Prof. Newton's edition of "Yarrell's British Birds," will find delight and instruction in the volume now issued by Mr. Seebohm.

The first part contains an account of the Birds of prey, and the Thrushes, and considerable novelty is introduced in the style of nomenclature of these two groups. First of all we notice that Mr. Seebohm gives up the idea of *Orders* in the class *Aves*. Although commencing with the Birds of prey, the time-honoured opening "Order Accipitres" is absent, and we are introduced to the family *Falconidæ* instead, and we consider that it is in the classification adopted and in certain points of the nomenclature that the weak spot lies in this otherwise admirable work.

Mr. Seebohm is the kind of man who would speak disrespectfully of the Equator! With unremitting energy he charges full tilt against what he considers the abuses of scientific nomenclature in the present day, and not content with heartily belabouring those who differ from him, he returns to the assault on every possible opportunity, "fights all his battles o'er again, and thrice he slays the slain." He is quite furious with the rules propounded by the Committee of the British Association, and rebukes the authors, promoters, and followers of these rules with unabated vigour, but with perfect sincerity, as is exemplified by the following sentence in his "Notice to Subscribers," where he writes:—"If I have criticised the work of any of my fellow ornithologists too severely, I ask their pardon, and hope that they will pay me back in my own coin by correcting my blunders with an unsparing hand. The object of all true scientific work is the elimination of error and the attainment of truth."

We can promise Mr. Seebohm that, as one of the authors most severely attacked in his volume, we shall accept the above challenge, and shall not hesitate to pay him back in his own coin when occasion arises, trusting to the strength of the late Marquis of Tweeddale's dictum, that it is "by the flails of disputation that the truth is threshed out." And yet this is not an easy book to criticise. There is so much that is elegant in the treatment of the subject, and the work is so evidently done *con amore*, that in reading it through one is apt to lose sight of the irritating attacks on one's own writings in the admiration which the general style of the book compels; nevertheless there are several points on which it is impossible to agree with the author.

To drop the idea of *Accipitres* as an Order, and treat the Birds of prey as a simple family, suggests that the author has only a limited acquaintance with this group in its entirety, and this is a failing which appears throughout Mr. Seebohm's work, viz. that he is apt to judge of the classification of birds from a knowledge of Palæarctic forms alone, without any consideration of the mass of birds which are extra-Palæarctic in their habitat. This remark would be perhaps unnecessary did not the author aim at such a high standard. Thus his families are provided with "Keys to the genera," which, as Mr. Seebohm is nothing if not seeking after natural affinities, may be supposed to give the author's matured opinion on the relations of the genera. We can only wonder, therefore, at the importance attached to the characters which ally *Falco* with *Vultur* (in the same primary section of the *Falconidæ*), and place the Ospreys as intermediate between the Falcons and the Swallow-tailed Kite. The Falcons and the Honey-kites are united by such forms as the Neotropical *Harpagus*, the Indo-African genus *Baza*, and other forms, but what *Pandion* has to do with any of them we fail to see entirely, and so far we have not seen any reason to modify our opinion expressed in 1874, that the Ospreys are co-ordinate with the Falcons and the Owls, and form an intermediate group between these two. We should have thought, too, that at least as good characters could have been found to separate *Neophron* from *Vultur*, as some of those employed by Mr. Seebohm for distinguishing other genera of his family Falconidæ.

In the much-vexed question of the Jer-Falcons Mr. Seebohm brings in his favourite theory of interbreeding, and accounts for the variation in plumage between the different races on this score with much ingenuity and some show of success, but we must totally dissent from his view of the Iceland Falcon being an intermediate form (*F. gyrfalco-candicans*). To our mind it is quite as good a race as the true Jer-Falcon of Scandinavia, and has a perfectly distinct habitat. In Greenland the case may be different, and it is by no means improbable that the resident Jer-Falcon of Southern Greenland, *Hierofalco hoelboelli*, Nob., sometimes crosses with the Arctic white Jer-Falcon (*H. candicans*), and that the result is seen in those specimens which are so numerous in collections, and whose exact specific position it is difficult to define; nevertheless fully adult birds, both of *H. candicans* and *H. hoelboelli*, are very easily recognised, but Mr. Seebohm's theory of hybridisation carries a strong probability.

In the article on the Peregrine Falcon the author sounds the first note of the trumpet which is to carry the charge into the enemy's lines and work havoc and destruction among the followers of the British Association rules of nomenclature. Mr. Seebohm asserts (and he is probably right) that the *Falco gentilis* of Linnæus, founded on Albin's Falcon Gentle, is absolutely the oldest-known name for the Peregrine, if the above rules are to be carried out to the bitter end. In the year 1767, a posthumous work by Gerini, who cuts a great figure throughout Mr. Seebohm's book, contained the name *Falco peregrinus* for the species, and as this is also the best known one, it is adopted by Mr. Seebohm as being that "auctorum plurimorum." By the simple process of using that name which has been employed by the majority of standard ornithological writers, the author settles all vexed questions as to priority, and does away with the difficulties of nomenclature arising from the discovery of a prior name in some long-forgotten "musty tome" by some diligent bibliographer. In the present case Gerini's book cannot be invested with the authority which Mr. Seebohm claims for it, because, as Prof. Newton has lately shown, the work was the result of the labours of three *collaborateurs* who published it in 1767, Gerini himself having died in 1751. The work is generally quoted by authors as the "Storia degli Uccelli."

We must candidly confess that Mr. Seebohm's plan of selecting the best known names for a species of bird has much to recommend it, and in the present volume the result is in general satisfactory, as it restores to many of the common European species the names by which they are most familiar to the general public. At the same time this rule of adopting the nomenclature *auctorum plurimorum* requires great care in its application, and it will probably be found to work better in the case of European birds than in the less-studied species of other countries. The whole subject is deserving of earnest thought, but for our own part we cannot entirely free ourselves from the idea that a certain amount of injustice will be done to the labours of many of the early writers in ornithology whose names have been overlooked by their successors, but who scarcely deserve to be passed over entirely, as their work might be up to the standard of knowledge of the times in which they lived. We cannot help seeing throughout Mr. Seebohm's volume that justice to the labours of the forerunners in ornithological science is *not* tempered with mercy to those who have endeavoured in all sincerity to fix the earliest recognisable names to the species of European birds. We must regret

that we have not space to give extracts from the many charming accounts of the habits of our English birds of prey, which have certainly not been surpassed by any modern writer. We have already alluded to the anomalous position given to the Osprey in Mr. Seebohm's classification, and we notice that in the characters which he assigns to the genus (p. 54) he does not refer to the skeleton, which is so essentially Owl-like in structure. The author calls attention to a very serious slip made by ourselves in the "Catalogue of Birds" with regard to the Rough-legged Buzzard (*Archibuteo lagopus*). We were certainly in error in placing this bird with the genus *Buteo*, and indeed the woodcut of the reticulated tarsus convicts us on the face of it; but we strongly doubt the correctness of Mr. Seebohm's relegation of the species to the genus *Aquila*, and we hardly think that Dr. Gadow's evidence as to the resemblance of certain points in the anatomy of the genera *Aquila* and *Archibuteo* was intended to suggest that they were closely enough allied to be considered inseparable. On p. 134 we are told that "ornithologists seem to have a fatality for making petty blunders." This probably accounts for Mr. Seebohm's admitting (p. 130) a woodcut of the nest of the Hen Harrier with the bird appearing in the background about the size of a Song Thrush. Perhaps Mr. Whymper, the artist who has drawn this otherwise pretty sketch, will, like Mr. Hanhart, who has done the plates of the eggs, "get better as he improves." (*Vide* the "Notice to Subscribers.")

Passing on to the family *Strigidæ* or Owls, we find with regret that Mr. Seebohm has once more ruthlessly destroyed the simplicity of nomenclature in the European species, and this on the authority of the "Storia degli Uccelli," whose fourfold authorship would surely be more than sufficient to place the book out of court. The genus *Aluco* is once more invoked for the Barn Owl, *Strix* is restored to the Tawny Owl as well as to the Long-eared Owl, Short-eared Owl, and Tengmalm's Owl, and the Snowy Owl and the Hawk Owl are placed in one genus, *Surnia*. This classification of the Owls is by far the most disappointing portion of Mr. Seebohm's book, and ornithologists will be inclined to view with suspicion the ideas of an author who, in endeavouring to upset the rules of the British Association, requires them to pin their faith to a system which would lead to such a result as is here offered to us. Gerini's "Ornithologia Methodice Digesta" may have gone down a hundred and forty years ago, but in the present day it appears to be "*Chaos, rudis indigestaque moles*," which the stomachs of the present generation of ornithologists will not be found strong enough to assimilate. A little woodcut is appropriately inserted as a tailpiece on p. 182, which represents the author coming to grief on a downhill path!

In the account of the *Passeridæ*, or Singing Birds, another suggestive tailpiece at once meets our eye at p. 199: it represents a peaceful scene on a river, and is probably placed there as emblematical of the joy of the author at finding himself once more in smooth waters. The rest of the volume is occupied with an account of the Thrushes and Warblers, Chats, Redstarts, and Flycatchers, with which birds Mr. Seebohm possesses an acquaintance beyond that of any of his contemporaries; and no one who reads his book will find fault with this portion of the work, which appears to us to be in every way excellent. We unhesitatingly express our opinion that since the time of Macgillivray no such original book as Mr. Seebohm's has been published on British ornithology, and, in spite of a few less satisfactory illustrations, we think that the figures of the eggs are by far the best that have yet been given. We have ourselves too often run counter to the rules of the British Association Committee to allow of a suspicion of our complete sympathy with these rules, and Mr. Seebohm has done much to prove their unworkable character in many instances, but at the same time his strong expressions with regard to some of their most conscientious supporters seem to us likely to lessen the respect with which many of his incontrovertible strictures would otherwise have been received.

Another most useful ornithological work has also just made its appearance in Mr. Eugene Oates's "Handbook to the Birds of British Burmah." [1] Although less ambitious in its scope than Mr. Seebohm's work above noticed, it is nevertheless a very complete *résumé* of the ornithology of the country of which it treats, and it forms one of those useful volumes which appear from time to time from the pens of hardworking ornithologists, which bring into one focus the results of many scattered essays in various journals. It must not be supposed, however, that Mr. Oates's work has been confined to the incorporation of the labours of his predecessors, for although he has gathered together into one compass the results of the travels of Mr. Davison and Capt. Bingham in Tenasserim, and of Capt. Wardlaw Ramsay in Karennee, the book is also enriched with an account of his own personal experiences during a fourteen years' residence in Pegu. One great characteristic of this book is its conciseness. In the present volume of 430 pages, four hundred species are disposed of, and yet the principal references are given, as well as descriptions of all the species. In fact, the book quite comes up to our idea of what a model "handbook" should be, and there is no doubt that it will be simply invaluable to the collector in British Burmah, within whose reach it is placed by the exceedingly modest price at which it is published. All workers in the field of Indian and Indo-Malayan ornithology will not be able to do without this most useful volume.

R. BOWDLER SHARPE

THE AURORA BOREALIS [2]

III.

THE "*Utströmnings*" *Apparatus*.—On the top of a mountain, or in a spot situated so high that it commands the surrounding country within a radius of some 5 kilometres, the apparatus, which I have termed an "utströmnings" apparatus, should be erected. This instrument consists of a copper wire, at least 2 mm. in diameter, laid out on insulators fixed on poles 2 metres in height, along which points or nibs of copper or brass are attached at every half metre in such a way that they always point upwards. The wire is, I believe, arranged with most advantage as shown in the subjoined Fig. 1. If the wire begins at o, and the distance oo′ is = 18 metres, the total surface area of the apparatus will be = 324 square metres. The letter *i* indicates insulator.

The length of the wire is, therefore, 194 metres, and the number of insulators, if one insulator is attached in the centre of each outer coil, = 27.

The insulators should be of a peculiar construction, so that they would, under all conditions, even when covered by hoar frost, be perfectly efficient. The kind shown in Fig. 2, based on the principle of M. Mascart's insulator, appears to me to be the most serviceable.

This diagram shows the vertical section of the insulator attached to the pole. *ab* is a glass tube 7 mm. thick, 5 cm. in diameter, and 20 cm. in height. This tube is soldered to the bottom of the jar *cdef*, the outer diameter of which is 11 cm., and height 13·5 cm., and is, at the side, 10 cm. from the bottom, provided with an opening o (2 cm. in diameter), which can be closed with a cork. Above the tube, *ab*, the bell, *mnn′* is affixed, which is provided with arms for the coiling of the wire. In the cork, *o*, a U-shaped glass retort, with short arms pointed downwards, is inserted, and if the retort *fede* is filled

[1] "A Handbook to the Birds of British Burmah, including those found in the adjoining State of Karennee," by Eugene W. Oates, Executive Engineer, Public Works Department of India (British Burmah). London: R. H. Porter, 6, Tenderden Street, W., and Dulan and Co., 1883.

[2] Continued from p. 109.

with sulphuric acid, the outer surface of the glass tube, *ab*, will be kept dry, and almost completely insulated. The distance between the jar and the bell should be as great as possible, in order that the hoar-frost may not form a bridge across the intervening space.

From this apparatus a telegraph wire is led on poles

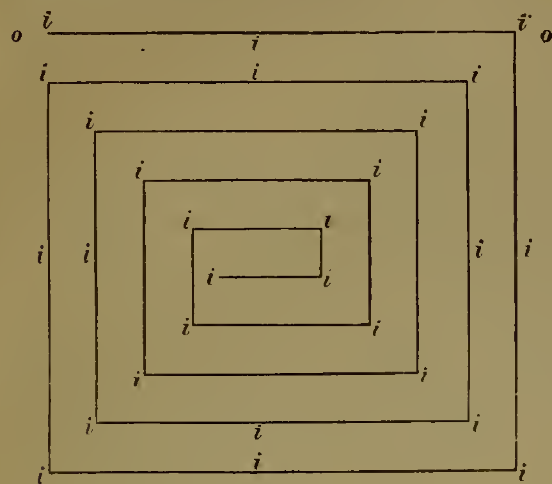

FIG. 1.

provided with insulators to a convenient chamber of observation. The conducting wire may, when the above-described kind of insulators is used, be an ordinary iron wire 2 mm. in diameter. The poles should be at most 40 metres apart.

The galvanometer should be constructed with a great

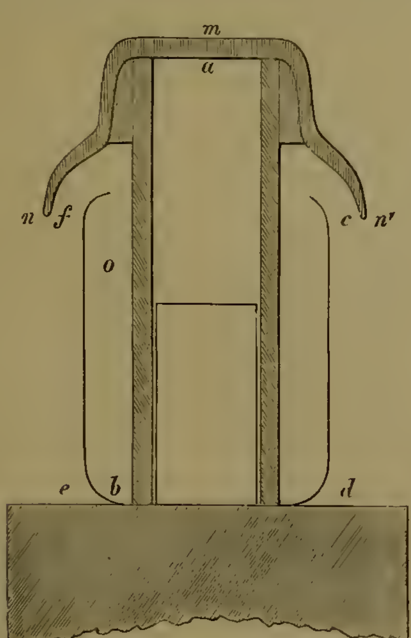

FIG. 2.

number (about 10,000) coils, and be provided with a pair of astatic needles, near which the mirror is affixed. In order to avoid too great oscillations, the needles should be hung side by side on fine threads of cocoon silk, the distance between the ends of the threads may be regulated according to circumstances. The readings should be made with a telescope and scale. It is besides clear that the conductive resistance of the galvanometer should be exactly measured, and that the readings of the instrument should be verified, as, for instance, with an inductor whose action on the galvanometer has been ascertained in absolute measure. For this purpose an ordinary Daniell's element may serve, and may in fact be the best, as a similar element should also be used for the actual measurements. If an iron wire is used it must of course be replaced with one of copper near the chamber of observation. The earth conductor of the current is a zinc disk about 4 square decimetres in area. The theory of the apparatus is this:—The entire quantity of electricity which is suffused in a certain part of the atmosphere which is situated above a certain horizontal plane, as that formed by the points in the "ütströmnings" apparatus, produces in each one of these points an *electromotive force*. And if the potential of these quantities of electricity on all the points be denominated as V_a, and the potential of the aggregate electricity on the zinc disk as V_z, the electromotive force E will be—

$$E = V_a - V_z,$$

and the strength of the current i

$$i = k\frac{V_a - V_z}{R},$$

where R denotes the whole conductive resistance, and k a constant dependent on the construction of the galvanometer, &c.

Generally, V_z is assumed $= 0$; but this is, in the present case, not correct; we therefore put—

$$i = k\frac{E}{R}.$$

If a constant element is introduced into the current, we have, if the electromotive force is denominated e, and the internal resistance of the element is not taken into account—

$$i_1 = k\frac{e}{R},$$

when i_1 means the intensity of the current which is created by the galvanic element.

If the positive pole is turned first against the "utströmnings" apparatus, we obtain—

$$i - i_1 = \delta,$$

and if the negative pole is turned against it—

$$i + i_1 = \delta',$$

i.e. if δ and δ' means the deflexion of the galvanometer in each case.

We obtain therefore in i a measure of $\frac{E}{R}$, and in i_1 a measure of $\frac{e}{R}$. If the deflexions are always reduced to the same value for $\frac{e}{R}$, which is easily done as e is constant, we obtain measures capable of being compared with E or $V_a - V_z$.

In the deflexions observed when a constant galvanic element is introduced into the circuit, one obtains, when the element is turned in the first instance with the positive pole against the "utströmnings" apparatus, and in the second against the earth-plate, a relative measure of the potential due to induction in the air on the particular occasion. From this it will appear that the observations should always be effected in the following manner:—

1. With the constant element in the current—
   (*a*) With the positive pole against the apparatus.
   (*b*) With the positive pole against the disk in the earth.
2. Without the element in the current—
   (*a*) First deflexion.
   (*b*) Constant deflexion.

3. With the constant element in the current—
   (a) With the positive pole against the apparatus.
   (b) With the positive pole against the disk in the earth.

The deflexions obtained will give the particulars required for an easy calculation of the strength of the current from the atmosphere to the earth.

I am fully aware that several details of this method may be open to discussion, but I do not deem others than the following of any great importance, viz. that as the intensity of the current is greatly dependent on the condition of the points, a gradual oxidation of the same will have the effect of causing an alteration in the current. This alteration also takes place in the strength of the current from the constant element, so that even the deflexions caused by the same will always be a measure of the aggregate potential due to induction, both through the points and in the air.

As it is not always possible to calculate the extent of the deflexions, an instrument permitting part of the current to be shunted should be employed. When the apparatus is erected care should be taken that the height between the disk in the earth and the apparatus is at least 180 metres; but experiments with disks at various elevations are of course of great interest.

From the account I have thus given of my experiments at Sodankylä, I think that all the subsidiary points which should be taken into account, as well as those questions which still await solution in connection with the aurora borealis, will be readily comprehended. It would, however, be of great advantage when making similar experiments to have two sets of apparatus; while thus measurements are being made with one, the variations in the current could be traced with the other, and thus the particulars requisite for a reduction to a fixed mean standard would be obtained.

SELIM LEMSTRÖM
Professor of the Helsingfors University

HISTORICAL NOTES IN PHYSICS

I.—*The Discovery of the Electric Light*

IN looking through an old volume of the *Journal de Paris*, I came across the following entry, for the date 22 Ventôse, An X. (March 12, 1802), which clearly relates to an exhibition of the electric arc light:—

"Le citoyen Robertson, auteur de la fantasmagorie, fait dans ce moment, des expériences intéressantes, et qui doivent sans doute avancer nos connoissances sur le *galvanisme*. Il vient de monter des piles métalliques, au nombre de 2500 plaques de zinc, et autant en cuivre rosette. Nous parlerons incessament de ses résultats, aussi que d'une expérience nouvelle qu'il a faite hier avec deux charbons ardens. Le premier étant placé à la base d'une colonne de 120 élémens de zinc et argent, et le second communiquant avec le sommet de la pile, ils ont donné, au moment de leur réunion, une étincelle brillante, d'une extrême blancheur, qui a été aperçue par toute la société. Le citoyen Robertson répétera cette expérience le 25."

The individual who thus came before the public was named Étienne Gaspard Robertson, a name suggestive of Scotch descent. He was better known for his "Phantasmagoria," exhibited a few years later in London. Of this invention a notice appears earlier in the volume from which the above passage is taken; and in an earlier volume of the *Journal de Paris* in the month "*Fructidor*, An viii.," there occurs a mention of some of his experiments on the *couronne de tasses* of Volta.

It is worthy of casual notice that in the number where Robertson's "Phantasmagoria" is advertised, the very next advertisement on the page is one of an exhibition to be given by Citoyen Martin at the Hôtel de Fermes, wherein as part of a "spectacle extraordinaire et amusant de physique," &c., was to be shown "l'expérience du télégraphie plus rapide que la lumière, d'un effet extraordinaire et amusant."

The usual date given for the invention of the electric light by Sir Humphry Davy is 1809; but I was aware that earlier notices existed both in Cuthbertson's "Electricity" (1807) and other works. I was also under the impression that some earlier reference to the matter existed in Davy's own works. The finding of this notice in the *Journal de Paris* induced me to consult the early volumes of the *Philosophical Magazine* and of *Nicholson's Journal*.

In the *Philosophical Magazine*, vol. ix. p. 219, under the date February 1, 1801, the following passage occurs in a paper by H. Moyes of Edinburgh, in which experiments with a voltaic pile or column are described:—

"When the above column was at the height of its strength its sparks were seen in the light of the day, even when taken with a piece of charcoal held in the hand."

In the *Journal of the Royal Institution*, vol. i. (1802), Davy describes (p. 106) some experiments on the spark yielded by the pile, and states: "When, instead of the metals, pieces of well-burned charcoal were employed, the spark was still larger and of a vivid whiteness." On p. 214 he describes and depicts an "apparatus for taking the galvano-electrical spark in fluids and aëriform substances." This apparatus consisted of a glass tube open at the top and having a tubulure at the side through which a wire tipped with charcoal was introduced, another wire, also tipped with charcoal, being cemented in a vertical position through the bottom.

But earlier than any of these is a letter printed at p. 150 of *Nicholson's Journal* for October, 1800. This letter is entitled "Additional Experiments in Galvanic Electricity, in a Letter to Mr. Nicholson." It is dated "Dowry Square, Hotwells, September 22, 1800," and is signed by Humphry Davy, who at that time was assistant to Dr. Beddoes at the old Philosophical Institution in Bristol. The letter begins thus:—

"SIR,—The earlier experimenters on animal electricity noticed the power of well-burned charcoal to conduct the common galvanic influence. I have found that this substance possesses the same properties as metallic bodies in producing the shock and spark,[1] when made a medium of communication between the ends of the galvanic pile of Signor Volta."

In none of these extracts, however, is anything said of the properties of the *arc* as a *continuous* luminous spark. These were made known in Davy's later researches. Yet the electric light attracted attention as we see before the special property of continuity was observed.

II.—*The Invention of the Telephone*

In the *Journal of the Physical Society of Frankfort-on-the-Main* for 1860–61 (p. 57) may be found a memoir on telephony by the galvanic current, in which its writer says: "I have now succeeded in constructing an apparatus by means of which I am in a position to reproduce the tones of divers instruments, and even to a certain degree the human voice." The inventor further says: "Since the length of the conducting wire may be extended for this purpose just as far as in direct telegraphy, I give to my instrument the name 'telephone.'" Towards the end of the memoir it is stated that until now it had not been possible to reproduce the tones of human speech with a distinctness sufficient to satisfy everybody: "The consonants are for the most part tolerably distinctly reproduced, but the vowels not yet to an equal degree." The author of the memoir in which these remarkable statements occur was Philipp Reis. The paper from which the preceding quotations have been taken contains many other points of interest, and in particular a com-

[1] Here Davy adds a footnote: "The spark is most vivid when the charcoal is hot."

parison of the action of the transmitting part of the instrument with that of the human ear upon which it was founded. The author says: "How could a single instrument reproduce at once the total action of all the organs operated in human speech? This was ever the cardinal question. At last I came by accident to put this question another way. How does *our ear* perceive the total (or

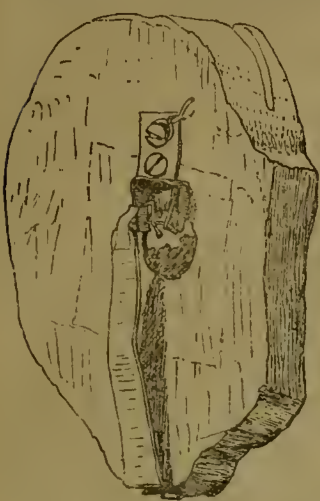

FIG. 1.

FIG. 2.

resultant) vibrations of all the simultaneously operant organs of speech?" He then goes on to describe the action of the auditory ossicles when made the recipients of sound-waves, and points out how they execute movements and exert forces upon one another in proportion to the condensations occurring in the sound-conducting medium and to the amplitudes of vibration of the tym-

FIG. 3.

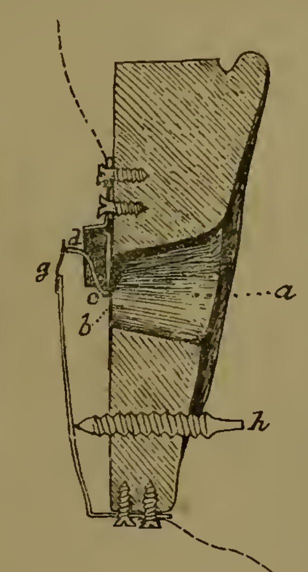

FIG. 4.

panum. Having stated this law of proportion between the cause and its effect, he goes on to speak of the graphic method of representing varying forces, such as those of sound-waves, by curves; and emphatically lays down that the ear is absolutely incapable of perceiving anything more than can be expressed by such a curve. After giving samples of undulatory curves corresponding to musical tones and to discordant sounds he makes the following significant remark: "So soon therefore as it is possible, at any place and in any manner, to set up vibrations whose curves are like those of any given tone or combination of tones, we shall then receive the same impression which the tone or combination of tones would have produced upon us. Taking my stand upon the preceding principles, I have succeeded in constructing an apparatus," &c. He concludes his paper by saying that the newly invented phonautograph of Duhamel may perhaps afford evidence as to the correctness of the views which he has asserted respecting the correspondence between sounds and their curves.

The actual apparatus figured in this memoir and exhibited to the Frankfort Society in October, 1861, is now in my possession; and I have also temporarily intrusted to me a still earlier experimental telephone made by Philipp Reis in the form of a model of the human ear.[1] This interesting instrument is depicted in its actual condition and size in Figs. 1, 2, and 3, and in section in Fig. 4. It is carved in oak-wood. Of the tympanic membrane only small fragments now exist. Against the centre of the tympanum rested the lower end of a little curved lever of platinum wire, which represented the "hammer"-bone of the human ear. This curved lever was attached to the membrane by a minute drop of sealing-wax, so that it moved in correspondence with

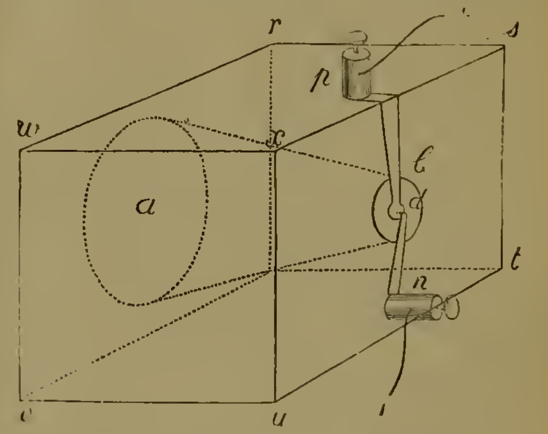

FIG. 5.

every movement of the tympanum. It was pivoted near its centre by being soldered to a short cross-wire serving as an axis. The upper end of the curved lever rested in loose contact against the upper end of a vertical spring, about 1 inch long, bearing at its summit a slender and resilient strip of platinum foil. An adjusting screw served to regulate the degree of contact between the vertical spring and the curved lever. Conducting wires, by means of which the current of electricity entered and left the apparatus were affixed to screws in connection respectively with the support of the pivoted lever and with the vertical spring.

If now any words or sounds of any kind were uttered in front of the ear, the membrane was thereby set into vibrations, as in the human ear. The little curved lever took up these motions precisely as the "hammer"-bone of the human ear does; and, like the "hammer"-bone, transferred them to that with which it was in contact. The result was that the contact between the upper end of the lever and the spring was caused to vary. With every rarefaction of the air the membrane moved forward, and the upper end of the little lever moved backward and pressed more firmly than before against the spring,

[1] The property of M. Léon Garnier, Director of Garnier's Institute at Fredrichsdorf, near Homburg, where Philipp Reiss was formerly Teacher of Natural Sciences.

making better contact, and allowing a stronger current to flow. At every condensation of the air the membrane moved backward, and the upper end of the lever moved forward, so as to press less strongly than before against the spring, thereby making a less complete contact than before, and by thus partially interrupting the passage of the current, caused the current to flow less freely. The sound-waves which entered the air would in this fashion throw the electric current, which flowed through the point of variable contact, into undulations in strength. Reis himself termed the contact-part of his telephone an interruptor. That it was not intended to operate as an abrupt make-and-break arrangement, as some persons have erroneously fancied, is evident; firstly, because the inventor introduced delicate springs to give a following-contact, and so prevent abrupt breaks from occurring; secondly, because abrupt breaks would have violated the fundamental principle to which he refers in the sentence immediately preceding his description of the instrument shown to the Frankfort Society, namely that of creating tones whose curves were like the undulatory curves imparted at the transmitting end of the instrument; thirdly, because (in another article) he described his instrument as opening and closing the circuit in proportion to the sound-wave, which obviously an abrupt "break-and-make" apparatus without a spring-contact could not possibly do. The mechanism which Reis thus invented —and which is substantially alike in all his instruments —might be appropriately described as the combination of a tympanum with an electric current-regulator, the essential principle of the electric current-regulator being the employment of a loose or imperfect contact between the two parts of the conducting system, those parts being so arranged that the vibrations of the tympanum would alter the degree of contact, and thereby vary the resistance offered at the point of contact to the passage of the current, and so regulate the strength of the current that it should magnetise and demagnetise the core of a distant electromagnet in a manner corresponding to the undulations of the tympanum of the transmitter.

The particular form of the instrument shown at Frankfort in 1861, and described in the *Journal*, is somewhat different from the "ear." The figure (5) and description are taken from the *Journal*.

"In a cube of wood, *r s t u v w x*, there is a conical hole, *a*, closed at one side by the membrane, *b* (made of the lesser intestine of the pig), upon the middle of which a little strip of platinum is cemented as a conductor of the current. This is united with the binding-screw, *p*. From the binding-screw, *n*, there passes likewise a thin strip of metal over the middle of the membrane, and terminates here in a little platinum wire, which stands at right angles to the length and breadth of the strip. From the binding-screw, *p*, a conducting-wire leads through the battery to a distant station."

In the original instrument there is also an adjusting-screw to regulate the contact, though this is not shown in the drawing.

The receiver used to reproduce the sounds transmitted by these telephones is also described in the memoir of Reis. It consisted of a steel needle surrounded by a coil of wire. This was at first set up for the purpose of increasing the sounds by resonance, upon the top of a violin; later it was mounted upon a pinewood box, to which still later a lid of thin pine was added against which the listener could press his ear. The sounds emitted by such a wire during magnetisation and demagnetisation were well known before, but to Reis is due the discovery that other tones than the natural vibration-tone of the wire could be electrically imposed upon it by the varying magnetising force of the current in the surrounding coil. Reis explained the reproduction of the transmitted sounds by supposing a magnetic attraction between the atoms of the steel wire to work synchronously with the fluctuations of the current. He later devised a different receiver in which an electromagnet was provided with an elastically mounted armature of iron which it threw into vibrations corresponding to those of the original sound-waves. With this apparatus and a transmitter with a small curved lever like that in the "ear," he was able (see Kuhn's "Handbuch der Angewandten Elektricitätslehre," 1866, p. 1021) not only to reproduce melodies with astonishing exactness, and single words as in speaking and reading (less distinctly), but even to transmit the inflexions of the voice expressive of surprise, command, interrogation, &c.

Considering how far these early researches were carried, it is remarkable that their historic value has been so greatly overlooked. SILVANUS P. THOMPSON

SQUALLS

IN a short calendar for the present year, issued by Dr. Gustavus Hinrichs,[1] are two interesting charts of the fronts of squalls passing over Iowa from north-west to south-east. He remarks that the lines between which ·5 inch and 1·0 inch of rain fell in one of these squalls on July 31, 1877, gradually diverge as the storm-front rolls down to the south-east, while bending more and more, so as strangely to recall the lines of equal timber in Eastern and Southern Iowa.

The lines showing the configuration of these squalls are very similar to those showing the shapes of the most extensive European squalls, and the almost complete parallelism between the chart of the squall above alluded to, and those[2] of the *Eurydice* squall, which traversed England on March 24, 1878, is worthy of the attention of meteorologists. Squalls of this description strictly deserve the name of "arched squalls" (apparently bestowed by English seamen on all squalls which are seen in perspective to rise as arches of cloud above the horizon), for when plotted out upon a chart they are found to be, at the period of their greatest development, *scimitar or crescent-shaped*, the central portion of the area of squall being in front of the right and left wings, and a chord of the arc so formed being commonly normal, or nearly so, to the isobars existing at the time. It seems probable that the most projecting portion of the line of clouds forming the front of the squall traverses the line of steepest atmospheric gradients, but of this no proof has yet been furnished. The strongest wind is, in any case, commonly experienced in the immediate front of the squall along the line traversed by the focus of the squall, and the greatest precipitation in the rear is also usually experienced along this line. There is one characteristic which the crescent-shaped squall shares with the very local squalls common in the temperate latitudes in the rear of a depression, viz. the violent down-rush of cold air experienced under the front of the squall-cloud, followed by a comparative calm in its wake. In the crescent-shaped squall there is a veering of the lower wind and a backing of the upper wind, sometimes to the extent of about eight points, which is not traceable in the more local squall. In the crescent-shaped squall a sudden increase of atmospheric pressure is experienced at the earth's surface at the time of the strongest rush of wind. This characteristic seems to be shared by the majority of squalls which occur in the Persian Gulf and in Northern India from the north-west, and also by many squalls in the Indian and China seas (which may possibly prove to be of the crescent-shaped type); and it is precisely analogous to the rise of barometer frequently noticed at inland localities in the temperate zones during a summer thunderstorm. It is, however, stated that in

[1] "Notes on the Cloud Forms and Climate of Iowa." Dr. G. Hinrichs, Director Iowa Weather Service.

[2] *Meteorological Magazine*, vol. xiii. p. 33; *Nautical Magazine*, vol. xlvii. 5.

the "tornadoes" of the Gold Coast (which are merely severe squalls) a fall of the barometer occurs. In some squalls, especially in the Indian and China seas, a change of wind occurs to nearly an opposite point of the compass, and in these instances there is sometimes a diminution of pressure [1] during the passage of the squall. These squalls I should regard as small typhoons.

The clouds which mark the front of an actual typhoon, as described by Dampier [2] and subsequent navigators, seem to be very similar to those which accompany the true squall, wherever observed. These consist of a dense curtain of ice-cloud in the higher regions of the atmosphere, usually permeated, except in the extreme rear, by mountainous cumuli from beneath, and having, when viewed at a distance, a very white and shining appearance. In the final stage of the squall, when it is diminishing in severity, these cumuli commonly disappear. A watchful outlook for these clouds, not least of all when coming off a high windward shore, may save many sailing vessels, as it might in all probability have saved the *Eurydice*, from destruction. NOTES

As we anticipated some weeks ago (p. 41), Prof. Lord Rayleigh has been nominated by the Council of the British Association as President for the Meeting at Montreal in 1884. The death of the late Prof. H. J. S. Smith having caused a vacancy among the vice-presidents elected at Southampton for the meeting at Southport in the present year, the Council have nominated Dr. J. M. Dawson, C.M.G., F.R.S., Principal of McGill College, Montreal, to be a vice-president.

PROF. HUXLEY'S Rede Lecture will have for its subject "The Origin of the Existing Forms of Animal Life: Construction or Evolution?" It will be delivered in the Senate House (Cambridge) on Tuesday next at noon.

THE death is announced of M. Charles Bresse, on May 22, at the age of sixty-one years. He was, since 1855, Professor of Mechanics in the School of the Ponts et Chaussées, and also for the last few years at the École Polytechnique.

A SERIES of conferences will be held in connection with the Fisheries Exhibition, in which the foreign commissioners, jurors, and others connected with or visiting the Exhibition, will be invited to take part. The first meeting of the Congress will be held on Monday, June 18, at 12 noon, when Prof. Huxley will deliver an introductory address. H.R.H. the Prince of Wales, K.G., has graciously consented to read a paper by H.R.H. the Duke of Edinburgh, K.G., entitled "Notes on the Sea Fisheries and Fishing Population of the United Kingdom," on Tuesday, June 19, at 12 o'clock. At all other conferences, the chair will be taken by the appointed chairman at 11 o'clock a.m. precisely. Papers will be read, and discussions on them will follow. The conferences will be held on Mondays, Tuesdays, Thursdays, and Fridays.

THE Company of Grocers have announced as the matter of competition for the first quadrennial discovery prize of 1000*l.* the following problem:—"To discover a method by which the vaccine contagium may be cultivated apart from the animal body, in some medium or media not otherwise zymotic: the method to be such that the contagium may by means of it be multiplied to an indefinite extent in successive generations, and that the product after any number of such generations shall (so far as can within the time be tested) prove itself of identical potency with standard vaccine lymph." The prize is open to universal competition, British and foreign. Competitors for the prize must submit their respective treatises on or before December 31, 1886, and the award will be made not later than May, 1887. In relation to this prize, as in relation to other parts of the Company's scheme in aid of sanitary science, the Court acts with the advice of a scientific committee which at present consists of the following members:—Messrs. John Simon, F.R.S., John Tyndall, F.R.S., John Burdon Sanderson, M.D., F.R.S., and George Buchanan, M.D., F.R.S.

A CORRESPONDENT in West Australia writes to us that the Exploring Expedition to Kimberly District, North-West Australia, to which Mr. E. T. Hardman, of the Geological Survey of Ireland, is attached as geologist, reached Roebuck Bay, Kimberly (lat. 18°.10′ S., long. 122° E.) on April 9, after a favourable voyage from Fremantle of ten days; all well, with the exception of a native who, in a fit of delirium, jumped overboard and was lost. Mr. Hardman proceeds with Mr. John Forrest, Surveyor-General, a well-known and experienced explorer, on a preliminary examination of the district for some months, and will then accompany the main party about to make a trigonometrical survey of the country along the Fitzroy River traced in 1879 by Mr. Alexander Forrest. The party, which consists of thirty-two, all told, with fifty horses, left Fremantle in the *Macedon*, on March 25, but were shipwrecked on Rottnest Island, and subsequently went on in the steamer *Rob Roy*. The field-work will be continued until the middle of next November, and will probably be resumed next year. Previous explorers pronounce this district to be one of the best in West Australia.

WE have received a communication from Herr Sophus Tromholt, dated Bossekop, May 18, in which he informs us that his work at Kautokeino having been finished he has paid a visit both to the Finnish station at Sodankylä and the Norwegian at Bossekop. Herr Tromholt now intends to proceed to Bergen, and promises, when settled, to send an account to NATURE of his final researches on the aurora borealis. He states, however, that at neither of the above-mentioned stations has any photograph of the aurora been obtained. Next winter, Herr Tromholt informs us, he will spend in Iceland, in order to proceed with his studies of the aurora borealis there, chiefly on the principle laid down by Prof. Lemström, and with the apparatus invented by the latter.

SIR JOHN LUBBOCK has given notice that he intends on Friday three weeks to draw attention to the fact that the Minister whose duty it is to bring forward the Educational Estimates has no power to appoint officers, and to move that it is desirable that there should be a separate department of education.

IT is stated that M. Jules Verne, the world-known novelist, will offer himself as a candidate to fill the chair vacated in the Académie Française by the recent death of M. Jules Sandeau.

AN Exhibition of Hygienic Dress and Sanitary Appliances, intended to illustrate as far as possible the aims and objects of the National Health Society, was opened by the Lord Mayor on Saturday afternoon, in Humphreys Hall, Knightsbridge. The Exhibition, which will continue for a fortnight, includes clothing, food products, everything connected with the sanitation of the house and hygienic decoration, appliances for the sick-room, home nursing, and home education, industrial dwelling and cottage hygiene, heating, lighting, and cooking apparatus, fuel, &c. Perhaps, however, the greatest attention will be devoted to the stands of the Rational Dress Society, and another close to it, where are shown examples of ladies' dresses made on purely hygienic principles.

TOURISTS with entomological proclivities who may be about to visit the Alps, Pyrenees, Norway, or other parts of Europe, will find Dr. H. C. Lang's "Butterflies of Europe" (L. Reeve

and Co.) very useful. So far as it has gone, indeed, it is the best book on the subject in the English language. Part xiii., just published, brings the work down to the larger Fritillaries, and is one of the most satisfactory so far as the plates are concerned.

THE Russian Chemical Society having established a competition for the best lamps for burning the intermediate oils of the Caucasian naphtha, which have a density from 0·860 to 0·875, has found that the four competing lamps satisfy the required conditions, the best of them being that of M. Kumberg. According to experiments made by Prof. Mendeléeff, the new lamps burn not only the intermediate oils but also a purified mixture of all distillations, the heavy greasy oils which have a density of 0·910 at 15° included. Like the American naphtha, the Baku naphtha would thus yield more than two-thirds (nearly three-quarters) of its weight of oils available for lamps, the oils from this last being far less dangerous than those of the former. It yields, besides, nearly 30 per cent. of greasy oils of great value.

M. YANKOVSKY mentions the disappearance of the spotted deer from the neighbourhood of Vladivostok. Before 1877 they were so numerous that flocks numbering forty and fifty were often seen, and their meat was cheaper than beef. Since the snowy winters of 1877 and 1878, however, during which they were hunted on a great scale, they have become very rare. It seems that other causes too have contributed towards diminishing their number. In 1878, after a great fire which consumed the whole of the depression around the lake of the Slavyansky peninsula, M. Yankovsky saw the valley dotted with the bodies of deer and antelopes. It will be a pity if a succession of mild winters does not give an opportunity to the spotted deer of multiplying again, as their number is already very limited, and the region they inhabit is very restricted, as it comprises only the sea-coast from Corea to the Bay of Olga.

NOTWITHSTANDING the active pursuit of the tigers in the South Usuri region, their number does not much diminish. In a communication to the Irkutsk branch of the Russian Geographical Society it is stated that in 1880 and 1881 no less than nine tigers were killed on the small space of thirty-five miles long, on the western coast of the Bay of Amur; and at the head of this bay five tigers were perceived at one time. The zoologist of the Society, M. Yankovsky, writes also that the South Usuri tigers do not seem to abstain from eating corpses and digging out graves as is generally believed.

ON May 19, at about 10 p.m., a remarkable aurora borealis was observed at Ludvika, in Sweden. It began as a faint band of light parallel with the horizon, which gradually grew broader and broader. The extraordinary feature of the phenomenon was, however, that this band had the appearance of an ice-covered lake on which the moon was shining. Promontories and shores covered with trees were seen, and also the faint outlines of farms. This phenomenon lasted about ten minutes, when the aurora changed into a suffused pink luminosity, like that of clouds near the setting sun.

A STRONG earthquake was felt throughout the state of Antioquoia at 6 p.m. on the 8th ult. Little damage was done in Medellin, although much alarm was caused and the walls of the cathedral were injured. In the town of Antioquoia the façade of the cathedral was thrown out of plumb, many of its columns were thrown down, and all the houses suffered more or less. In Santa Rosa the church steeple was injured and a number of houses rendered uninhabitable. In Aquadas the town hall was destroyed, and at Abejirral the church and a number of houses were injured. It was feared more disasters had occurred in districts which had not been heard from. The shock lasted more than two minutes, and appeared to move from the north to the south. This same shock was felt all over the isthmus, all along the Atlantic coast of Columbia, doing damage only at the mouth of the Atrato, so far as reported up to the present, and in the Magdalena Valley. It appears to have been the sharpest and most widely experienced since the great one of September 7 last year.

TELEGRAMS from Batavia state that Mount Karang in the Straits of Sunda is in full eruption. The shocks are heard several hundred miles away. It is now two hundred years since the last eruption of this volcano. The mountain is situated on the island of Krakatoa, near Anjer in the Straits of Sunda, and as it is in the path of sailing vessels from Europe to the East, which generally call at Anjer point for provisions and orders, we may shortly expect details of the eruption.

A CORRESPONDENT writes:—During the last ten years much has been written on the origin of the jade objects found in America and Europe, no raw materials of the stone having yet been discovered out of which the articles could have been manufactured. Prof. H. Fischer of Freiburg in Baden therefore brought forward the hypothesis, supported by several of his scientific brethren, that the jade objects of America had been transported thither from Asia in prehistoric times, when Mongolian tribes settled in the New World, and that the intercourse of trade had later acted in the same manner. For Europe, where thousands of those objects have been found, the Aryans had done this service, when wandering from the very heart of Asia to the west, the source of the jade objects of both continents being Asia, where deposits of the mineral are known to occur in Siberia, Turkestan, and Burmah. Recently Dr. Meyer of Dresden has energetically opposed these views in a large folio work containing many plates, and has come forward with the opinion that the jade sources of Europe and America yet remain to be discovered. As to America we are glad to hear that this much simpler and more reasonable explanation of the problem has now been verified, the Smithsonian Institution of Washington lately having received from Louisiana an immense number of objects of jade, among them implements, knives, and other articles, many having an admirably high finish, and with them a considerable quantity of the stone of which the objects were made. We do not doubt that similar discoveries may soon be expected in Europe, especially in Switzerland, and that we shall succeed in ascertaining the exact districts where the mineral is to be found.

WE are glad to see that there is at last some prospect of the immediate publication of Mr. W. Colenso's Maori-English Lexicon, which was submitted to the New Zealand Government nearly eight years ago. A specimen sheet of twenty folio pages has recently been printed and presented to both Houses of the General Assembly by command of the executive authorities. From this specimen it is evident that the work is of an encyclopædic character, embodying a vast amount of information collected from original sources on the languages, ethnology, traditions, religions, habits, and customs of the Polynesian races. The plan is at once simple and comprehensive. The various meanings of each word are first given in large type, and each meaning is then illustrated by one or more passages in small type from the native poems, myths, legends, proverbs, and colloquial usage. Thus nearly four pages are devoted to the different significations and grammatical applications of the single word *a*, which plays such an important part in all the Polynesian dialects. To the particle *atu* as many as thirty distinct meanings are assigned, and these meanings are illustrated by no less than seventy-two quotations from the various sources above indicated. In some cases the quotations are Englished, and it would certainly be satisfactory if this could be done uniformly. In the English-Maori part the same plan is adhered to, only here quotations

illustrating the different senses of the English words are omitted as unnecessary. Should the work be carried out on these lines it will enable the student to wait somewhat more patiently for the appearance of Mr. Whitmee's long-promised Comparative Dictionary of the Polynesian Languages.

THE Minister for Postal Telegraphy will ask from the French Parliament the credits required for connecting by a cable Saigon to Haïfong, the principal seaport of Tonquin, and Haifong to Hanoi by another line laid down in the bed of the Red River.

AT the Polytechnic, which is now occupied by a Young Men's Christian Institute, there was recently an exhibition of drawings, and works of art and manufactures, executed wholly or in part by the members of the institute and the students at the numerous classes held there. Most of the exhibits show proofs of the usefulness and success of the institution. The exhibition included also many valuable works of art and a very costly and interesting collection of Japanese, Chinese, and Indian curiosities lent for the occasion by Mr. Quintin Hogg and other friends of the institute.

THE Oxford University Junior Scientific Club held a very successful *conversazione* in the University Museum on Friday evening last.

PROF. DEWAR, F.R.S., will give an experimental discourse on the Chemistry of the Electric Discharge at the last Friday evening meeting on June 8 at the Royal Institution.

THE additions to the Zoological Society's Gardens during the past week include two Pig-tailed Monkeys (*Macacus nemestrinus* ♂ ♀) from Sarawak, presented by His Highness the Rajah of Sarawak; an Egyptian Cat (*Felis chaus*) from India, presented by Mr. W. R. Glyn Griffiths; three Common Kingfishers (*Alcedo ispida*), British, presented by Mr. Frederic Houghton; a Barbary Ape (*Macacus inuus*) from North Africa, four Elliot's Pheasants (*Phasianus ellioti* ♂ ♂ ♀ ♀) from China, five Ceylon Terrapins (*Clemmys trijuga*) from Ceylon, four Bungoma River Turtle (*Emyda granosa*) from India, four Lacertine Snakes (*Cœlopeltis lacertina*), a Horseshoe Snake (*Zamenis hippocrepis*), a Pleurodele Newt (*Pleurodeles walti*), South European, a Red-legged Partridge (*Caccabis rufa*), European, deposited; a Buffon's Touracou (*Corythaix buffoni*) from West Africa, two Bronze-winged Parrots (*Pionus chalcopterus*) from South America, two Varied Hemipodes (*Turnix varia*) from Australia, two American Siskins (*Chrysomitris tristis*) from North America, two Black Larks (*Melanocorypha yeltonensis*) from Siberia, a Cerastes Viper (*Vipera cerastes*) from Egypt, purchased.

LOCAL SCIENTIFIC SOCIETIES

FOR some years past there has been a growing expression of desire of local scientific societies to be officially represented at the meetings of the British Association. The question is one of considerable difficulty and delicacy, and though it has been the subject of frequent discussion and some legislation, no measure has yet been carried that is satisfactory to all parties. Last year the subject was referred to the Council, who appointed a special committee, and this committee made on Tuesday its preliminary report. They asked in it for permission from the Council to circulate the report among the local societies in order to obtain from them that response which is needed before the committee can feel themselves in a position to report finally, and *a fortiori* before the Council can take their report into consideration. This permission has been granted, together with that of free publication. A copy of the report will consequently be shortly sent to the various societies by the secretary, Mr. H. George Fordham, Odsey Grange, Royston, Cambridgeshire, with the request that their replies will be forwarded to him. But as the subject presses, and as the season is advancing and the annual sessions of societies are drawing to a close, the best method of bringing the report before the members of those societies is through the columns of NATURE. I therefore forward it at once. FRANCIS GALTON

June 6

Preliminary Report of the "Local Scientific Societies' Committee, consisting of Mr. FRANCIS GALTON (*Chairman*), *the* Rev. Dr. CROSSKEY, Mr. C. E. DE RANCE, Mr. H. G. FORDHAM (*Secretary*), Mr. JOHN HOPKINSON, Mr. R. MELDOLA, Mr. A. RAMSAY, Prof. SOLLAS, Mr. G. J. SYMONS, *and* Mr. W. WHITAKER, *appointed by the Council in compliance with the following resolution referred to the Council by the General Committee:*

"That the Council be empowered to appoint a Committee, as recommended in their Report adopted by the General Committee on August 23, in order to draw up suggestions upon methods of more systematic observation and plans of operation for Local Societies, together with a more uniform mode of publication of the results of their work. It is recommended that this Committee should draw up a list of Local Societies which publish their proceedings."

The Committee have communicated with all the Societies known to them which appear to fall under the designation of "Local Societies which publish their proceedings," giving to this definition a somewhat liberal interpretation, and they submit a tabular list of the publications with other particulars of those which have furnished replies. These societies are about 170 in number, and seem from their rules and publications to be centres whence local scientific information may conveniently be obtained.

The Local Societies differ widely in character. Those which are established in large towns, and are not particularly well situated for carrying on systematic local investigations, are often of high scientific rank, and their affairs are administered in a business-like manner by a regular staff. On the other hand, there are numerous smaller societies and field clubs, scattered over the country, which are excellently placed for conducting local investigations, but whose organisation is so incomplete that it has often been difficult to discover their official addresses.

In some parts of the country the smaller societies either group themselves into what is practically a federation, or else affiliate themselves to some large society in their district, and the Committee think that if the Local Societies generally could be induced to group themselves round what might be described as local sub-centres, it would not be difficult to devise methods of uniting the representatives of those sub-centres in the performance of interesting and important duties during the meetings of the British Association, with the final effect of establishing systematic local investigation throughout the country, and uniformity in the modes of publishing the results. The recommendations the Committee are about to make will tend wholly in this direction, because, although they have considered many plans of fulfilling their instructions in a direct manner that perhaps look well on paper, no plan recommends itself to them as superior to this indirect method in its capacity of producing valuable and durable effects.

The Committee do not suggest any new topics for systematic investigation, but confine themselves to giving a few examples of what these topics are, taken from a circular printed last year by a committee appointed at a conference of delegates of scientific societies: (1) *Underground Waters* (to record the height of water in wells, and its variations in level in different parts of the country). (2) *Erratic Blocks* (to record their position, height above sea, lithological character, &c.). (3) *Underground Temperature* (to investigate the rate of its increase downwards in various localities). (4) *Rainfall* (its measurement). (5) *Periodical Natural Phenomena* (to record time of flowering of certain plants, arrival of certain migratory birds, appearance of certain insects). (6) *Injurious Insects* (to record their appearance in unusual numbers, the injuries they cause, and the degrees of success in preventing them). The first three of these investigations were set on foot by Committees of the British Association, and the last three by societies or private individuals.

It can hardly be doubted that numerous systematic investigations of a local character will from time to time be carried on, and that their successful prosecution would result in important gains to science. Neither does it appear doubtful

that the successful prosecution of such investigations by the smaller Local Societies would be greatly encouraged and facilitated by the general interest shown in their work by the more influential societies in their neighbourhood, by a watchful oversight, a readiness to discuss and publish results, and by the personal influence of their leading members. The Committee offer the recommendations they are about to make in the trust that, if the Council are pleased to publish them, they will serve to remind the more important Local Societies of the high and useful function they are able to perform by entering into friendly and helpful relations with the small and scattered societies of their respective districts, and by offering themselves as their scientific representatives wherever representation may be necessary.

The Committee recommend that they be empowered to print and circulate among the Local Societies the following draft of suggested rules, to give an opportunity to those societies of taking that initiative without which no action on the part of the Association is likely to produce much effect. After the Committee have been informed of the views of these societies, they will be in a better position than they are at the present moment for appreciating at its true value the desire for cooperation which they believe to exist. They will also perhaps receive useful suggestions from the societies that have not occurred to themselves, and they will probably be in a position to submit their final recommendations before the approaching annual meeting.

"SUGGESTED NEW RULES, THE EXISTING RULES BEING ALTERED ACCORDINGLY.

"*Corresponding Local Societies.*

"Application may be made by any society publishing scientific memoirs to be placed on the list of Corresponding Local Societies of the British Association. These applications must be addressed to the Secretary, and be made on or before the second day of the annual meeting, and they must be accompanied with a copy of the publications of the Society during the preceding year.

"The Secretary shall transmit these applications to a Committee appointed by the Council for the purpose of considering them, as well as for that of keeping themselves generally informed of the annual work of the Corresponding Local Societies. This Committee shall make an annual report to the Committee of Recommendations, and shall suggest such additions or changes in the list as they may think desirable; but the final determination of the list will rest with the Committee of Recommendations, subject only to the conditions—(1) That the number of Societies on the list shall not exceed that which is prescribed by the Council; (2) that the intended removal of any Society from the list shall not take effect until immediately before the commencement of the next annual meeting.

"The privileges of a Corresponding Local Society shall consist in—(*a*) The insertion in the Annual Report of the British Association of an index, in such abbreviated form as the Council may sanction, of the titles of the scientific memoirs published by the Society during the previous year; (*b*) the right to nominate any one of its members, who is also a member of the British Association, as its delegate to the annual meeting of the Association, who shall have for the time the rights of a member of the General Committee.

"Before the delegate can enter into his rights, he must transmit to the Secretary of the British Association a copy of the publications during the previous year of the Society he represents. He must also fill up a schedule, that will be furnished to him by the Secretary on application. This schedule will ask for—(*a*) The names of the President and chief executive officer of his Society; (*b*) a list of the institutions, if any, in its neighbourhood with which it has official relations and whose interests it represents; (*c*) a brief report on the character, number, and results of any systematic local observations carried on during the past year, either by itself or by any of the institutions on the foregoing list: (1) at the instance of Committees of the British Association, (2) at the instance of other Societies or private persons; (*d*) such other information as may be thought desirable.

"The delegates of the various Corresponding Local Societies shall constitute a Committee, which shall be summoned by the Secretary of the Association to hold one or more meetings during each annual meeting of the Association, under a Chairman and with a Secretary appointed by the Council. The Secretaries of each Section shall be instructed to transmit to the Secretary of the Committee of Delegates copies of any recommendations forwarded by the Presidents of Sections to the Committee of Recommendations bearing upon matters in which the cooperation of Local Societies is desired; and the Secretary to the Committee of Delegates shall invite the authors of those recommendations to attend the meeting of the Committee and give verbal explanations of their objects and of the precise way in which they would desire to have them carried into effect, and to discuss difficulties that may be raised by any member of the Committee, so that the Delegates may be qualified on their return to bring those recommendations clearly and favourably before the notice of their respective Societies."

The Committee believe that the distinction accorded to a Local Society through its selection and formal recognition by the British Association as one of its Corresponding Societies, the advantage of a widely-circulated notice of its work in so important a volume as the Report of the British Association, and the honourable and useful duties assigned to its delegate, would give considerable value to the title.

They also anticipate that a Local Society, which had asked for and received recognition as the representative centre for the time being of the institutions in its district, would be thereby stimulated to exercise that very creditable and important function with increased zeal and efficiency. The result would be to strengthen the mutual relations of the larger and the smaller Local Societies, to insure the encouragement of any disposition to engage in systematic investigations, and to establish a practice of printing the scattered results obtained by the smaller Local Societies of any district in a consolidated form in the publications of their leading Society.

Finally, the Committee believe that the annual meetings of the proposed Committee of Delegates, under the chairmanship of a distinguished member of the Association, would have large influence in harmonising the action of their several Societies, and that it would offer a facility that does not now exist for the natural and healthy growth of a federation between remote Societies which have no more direct bond of union than through the British Association.

THE ROYAL OBSERVATORY

THE following are the leading points referred to in the Report of the Astronomer Royal to the Board of Visitors of the Royal Observatory, Greenwich, read at the annual visitation on June 2.

On the subject of Astronomical Observations Mr. Christie says:—

"The regular subjects of observation are the sun, moon, planets, and fundamental stars, with other stars from a selected list. The working catalogue of 2500 stars down to the fifth magnitude having been cleared off, a new working list of 2600 stars, comprising all stars down to the sixth magnitude inclusive which had not been observed since 1860, has been prepared, and was brought into use at the beginning of March. About 1200 stars were observed in 1882, but amongst these there are nearly 500 single observations, necessitating careful comparison with catalogue place for the detection of any mistakes of observation or reduction. The labour thus entailed is considerable, and efforts will be made to obtain in this and each future year at least two observations of every star observed.

"The following statement shows the number of observations with the transit-circle made in the year ending 1883, May 20:—

Transits, the separate limbs being counted as separate observations	4488
Determinations of collimation error	354
Determinations of level error	323
Circle observations	4485
Determinations of nadir point (included in the number of circle observations)...	298
Reflection observations of stars (similarly included)	484

"Comet *a* 1882 has been observed seven times on the meridian since the date of the last Report, and Comet *b* 1882 has been observed three times.

"As regards the computations—

Clock times of transit over the true meridian after all corrections for instrumental errors are prepared to	1883, May 13
Clock errors and rates are determined to ...	May 5
Mean R.A.'s on 1883, January 1, are formed to...	April 25

"The investigation of personal equations has been completed for the year 1882, the results being very accordant with those found in the preceding year.

"The circle observations are completely reduced so as to form mean N.P.D. for 1883, January 1 to April 21, apparent Z.D.'s being formed to April 28.

"From the beginning of this year a correction of $-0''\cdot39$ has been applied to the results of the nadir observation to make them agree in the mean with the results of reflection observations of stars. This correction has been deduced from a comparison of the nadir results throughout 1822 with corresponding reflection results for stars north and south of the zenith. The discordance appears to be increasing, and its source has not yet been traced. It does not appear to originate on this occasion with the microscope-micrometer or telescope-micrometer, and it is not connected with the extension of the range of observation of stars by reflection. The discordance, which was insignificant in 1878, amounting only to $-0''\cdot03$, has gradually increased since, being $-0''\cdot10$ in 1879, $-0''\cdot29$ in 1880, $-0''\cdot30$ in 1881, $-0''\cdot39$ in 1882, and for the first four months of this year $-0''\cdot58$.

"Determinations of flexure have been made on 1882, December 30, and 1883, May 10 and 18, the resulting values being $-0''\cdot07$ and $-0''\cdot78$ and $-0''\cdot33$. The observations on May 18 were not altogether satisfactory, as the sun was shining during the second set of measures. The values resulting from the first and second sets respectively are $-0''\cdot72$ and $+0''\cdot05$. There is apparently nothing in the observations on May 10 to account for the exceptionally large value found on that day. No correction for flexure, as apart from the correction for R – D, has been applied to the observations.

"The correction for R – D, the error of assumed colatitude, and the position of the ecliptic have been investigated for 1882. For the planetary results, errors of R.A. and N.P.D. have been formed, but the heliocentric errors have not yet been computed.

"The reflection observations of stars available for investigation of the R – D discordance extend from Z.D. $71\frac{1}{2}^\circ$ north to Z.D. $70\frac{1}{2}^\circ$ south, and the discussion of these shows discordances steadily increasing from the zenith towards the horizon, and amounting to $-1''\cdot58$ for the group at Z.D. $68\frac{1}{4}^\circ$ north and to $+1''\cdot66$ at Z.D. 70° south, a correction of $+0''\cdot16$ sin Z.D. having been first applied to the reflection observations for inclination of the vertical at the mercury trough. It is quite evident that the discordances do not follow any such law, as $a + b \sin z \cdot \cos^2 z$, which was used from 1862 to 1880. Assuming the law $a + b \sin z$, which was adopted in the years preceding 1862 and in 1881, the R – D correction for 1882 would be $+0''\cdot07 + 0''\cdot42 \sin z$, and for the sake of continuity in the system of reductions this correction has been provisionally adopted for use in 1882. But the discordances between this formula and the observed quantities increase regularly from the zenith towards the horizon, amounting to half of the observed quantities at Z.D. 50° to 60°. The formula $+ 0''\cdot08 + 0''\cdot29 \tan z$ represents the observations better, though even this does not give sufficiently large results at large zenith distances. In this discussion corresponding reflection and direct observations made on the same day have alone been used.

"The value found for the colatitude from the observations of 1882 is 38° 31′ 21″·93, very slightly larger than the assumed value; the correction to the tabular obliquity of the ecliptic is $+ 0''\cdot44$; and the discordance between the results from the summer and winter solstices is $+ 0''\cdot37$.

"The mean error of the moon's tabular R.A. from observations with the transit-circle in 1882 is + 0·82s.

"The following observations have been made with the altazimuth from 1882, May 20, to 1883, May 20:—

Azimuths of the moon and stars	317
Azimuths of the azimuth-mark	228
Azimuths of the collimating-mark	216
Zenith-distances of the moon	176
Zenith-distances of the collimating-mark	214

"Azimuths and zenith-distances of Comet *b* 1882 were observed on a single day.

"The altazimuth observations are completely reduced to May 6, so as to exhibit errors of moon's tabular R.A., N.P.D., longitude, and ecliptic N.P.D. The restriction of the observations, and the limitation of the computations to 0·01s. and 0″·1 have made these reductions comparatively light.

"The moon's diameter has been measured—

With the transit-circle, twice in R.A., 17 times in N.P.D.
With the altazimuth, 4 times in azimuth, 10 times in Z.D."

On the subject of Equatoreals Mr. Christie states:—"A very valuable addition has been made to the instruments of the Royal Observatory by the gift of the Lassell two-feet reflecting equatoreal, which has been generously presented by the Misses Lassell. The exceptional qualities of this fine telescope (with which Hyperion was discovered in 1848) are well known, and there could be no hesitation in accepting on the part of the Admiralty the offer of such a valuable gift. The instrument was removed from Maidenhead early in March, and has been erected in the south ground, where it commands a nearly unobstructed view of the sky to within about 5° of the horizon. A circular building 30 feet in diameter, has been erected for the Lassell telescope, and the construction of a suitable dome is authorised. There are two large mirrors available for use, and I contemplate taking advantage of the firm mounting and perfect clock movement of the south-east equatoreal to mount the spare mirror on this instrument, attaching it to the tube of the refractor, so as to have on the same mounting a refractor and reflector with their axes parallel. The former would be available for eye observation, whilst the latter could be used on the same object for physical work, spectroscopic or photographic. The Lassell telescope itself would be well suited for observation of faint satellites and comets which are beyond our present instrumental means.

"The observations of the solar eclipse of 1882, May 17, with the south-east equatoreal are completely reduced, and the final equations have been solved.

"The spectroscopic observations during the past twelve months have been somewhat restricted through the pressure of the photographic reductions at a time of maximum of sunspot frequency. The solar prominences have been observed with the half-prism spectroscope on eight days, and four sun-spots have been examined on eight days with reference to the broadening of lines in their spectra. The spectrum of the great spot of 1882, November 12–25, showed some remarkable reversals of the lines of hydrogen and sodium, and an extraordinary displacement of the F line.

"As regards the determination of motions of stars in the line of sight, 142 measures have been made of the displacement of the F line in the spectra of 23 stars, and 26 measures of the b_1 line in 9 stars. The observations of Sirius during the past winter tend on the whole to confirm the impression that the rate of recession of this star has diminished progressively since 1877, and that the motion is now on the point of being converted into one of approach.

"The spectrum of Comet *a* 1882 was examined on three nights, that of the great Comet *b* 1882 on three nights, and that of Comet *a* 1883 on one night The spectrum of the first-named object showed the yellow sodium lines with great brilliancy just before perihelion passage. The spectrum of the aurora of 1882, November 17, was also examined.

"The spectroscopic observations of all kinds have been completely reduced to 1883, May 20.

"In the year ending 1883, May 20, photographs of the sun have been taken on 200 days, and of these 339 have been selected for preservation. There were 7 days on which the sun's disk was observed to be free from spots. The number and size of spots and faculæ continued to increase in a marked way till last November, when a group of spots of very unusual size appeared. Since that date, however, the sun has become more quiescent.

"Since the beginning of December, gelatine dry plates have been used instead of the old wet-plate process. They are more convenient in use, and appear to give as good average results. The photographs on a scale of 8 inches to the sun's diameter recently obtained in India, under the auspices of the Solar Physics Committee, are so successful that the Committee have recommended the general adoption of this scale, and I propose, as soon as we have a spare photoheliograph returned from the Eclipse Expedition, to have it altered in the same manner as the Indian photoheliograph, so as to obtain eight-inch photographs of the sun instead of four-inch.

"It was suggested in the last Report that the measurement of such of the Indian and other photographs as were required to fill up gaps in the Greenwich series might with advantage be undertaken here. This proposal has now been carried out, and 111 photographs for the period from 1881, December 22, to 1882, October 19, have been received from the Solar Physics

Committee, so that a record of the condition of the sun on 279 out of the 302 days in that interval is now presented. From 1882 October 20, eight-inch photographs were taken in India, and for the measurement of these a special micrometer has been ordered of Messrs. Troughton and Simms by the Solar Physics Committee.

"All the photographs received from the Solar Physics Committee have been measured in duplicate, and the measures have been completely reduced so as to exhibit heliographic longitudes and latitudes of spots, and areas of spots and faculæ, from 1881, December 22, to 1882, October 19, the end of the series of four-inch photographs.

"Magnetical Observations :—

"The course of observation continues the same as in former years, changes in the magnetic declination, horizontal force, and vertical force being continuously recorded by photography with the three magnetometers, whilst absolute values of magnetic declination, dip, and horizontal force are found by eye observation. Earth-currents in two directions nearly at right angles to each other are also photographically registered.

"A great improvement has been made in the photographic registration by the substitution in June last of Morgan and Kidd's argentic-gelatino-bromide paper with ferrous oxalate development for the old photographic process.

"The large temperature correction of the vertical force magnet has been reduced to less than one-fourth of its former amount by some alterations which were carried out by Mr. Simms last autumn. The effect of these alterations has been to reduce the correction for change of 1° Fahrenheit from 0·00088 of the vertical force to about 0·00020. The coefficient, has, however, still the opposite sign to that which would result from mere loss of magnetic power with increase of temperature. It is intended to make an attempt to still further diminish the temperature correction by shifting the magnet in its carrier so as to reduce the horizontal stalk and balance weight.

"It was remarked in the last Report that the earth-current registers frequently showed abnormal disturbance during rain. By the kindness of Mr. Lemard (the successor to the late Mr. C. V. Walker, as telegraph engineer of the South-Eastern Railway), the wires were repaired in February, and the rain disturbance seems now to have disappeared.

"The following are the principal results for magnetic elements for 1882 :—

Approximate mean westerly declination	18° 22′.
Mean horizontal force ...	3·913 (in English units). 1·804 (in metric units).
Mean dip	67° 33′ 33″ (by 9-inch needles). 67 34 34 (by 6-inch needles). 67 34 14 (by 3-inch needles).

"There has been considerable magnetic activity during the year, the month of November, which was characterised by the appearance of a very large sunspot, being particularly disturbed with remarkable magnetic storms on November 17, 19, and 20, and many interesting cases of lesser disturbance. The magnetical changes in November are so interesting in relation to the accompanying outburst of sunspots that it seems desirable to have the registers for a great part of the month as well as for other days of magnetic disturbance in the year lithographed in the 'Greenwich Magnetical Results for 1882' on a reduced scale. The character of a disturbance would, I think, be much better shown by a reproduction of the curves traced on thf photographic sheets than by tables of numerical values oe ordinates. I am making inquiries as to the practicability of using some anastatic process, which would not be very expensive.

"The magnetic disturbances on October 2 and November 17 were accompanied by brilliant auroras.

"Particulars of magnetic disturbances are regularly communicated to the *Colliery Guardian* newspaper for the information of mining surveyors.

"Meteorological Observations :—

"On the occasion of the gale of 1882, October 24, a velocity of 64 miles an hour was registered with Robinson's anemometer for two successive hours, being greater than any velocity previously recorded here, but the greatest pressure registered with the chain was only 29 lbs on the square foot, whilst on 1882, April 29, a pressure of 49½ lbs. was recorded with the copper wire at a time when the velocity was only 50 miles an hour.

"The observations of temperature of the Thames have recently been resumed under the charge of the Corporation of London, who have instructed Mr. G. J. Symons to arrange details. The observations are now made at the end of one of the jetties of the Foreign Cattle Market at Deptford, where a record is to be kept (by means of two Six's thermometers) of the daily maximum and minimum temperatures of the Thames at a depth of 2 feet below the surface, and also near the bottom of the river. Mr. Symons has arranged that these observations shall be regularly communicated to the Royal Observatory to be included in the meteorological table published weekly in the Registrar-General's Reports.

"The mean temperature of the year 1882 was 49°·6, being 0°·1 lower than the average. The highest air temperature was 81°·0 on August 6, and the lowest 22°·2 on December 11. The mean monthly temperature was above the average from January to May, then below until September. In October, November, and December it differed little from the average.

"The mean daily motion of the air in 1882 was 306 miles, being 27 miles greater than the average For the month of November the mean daily motion was 449 miles, being 159 miles above the average. The greatest daily motion was 758 miles on November 4, and the least 30 miles on December 11. As already mentioned, the greatest hourly velocity was 64 miles an hour, and the greatest pressure (with the chain) 29 lbs. on October 24.

"During the year 1882 Osler's anemometer showed an excess of 11 revolutions of the vane in the positive direction N., E., S., W., N., if all the turnings are counted (as has been the practice in former years); or of 23 revolutions in the positive direction if the turnings which are evidently accidental are excluded.

"The number of hours of bright sunshine recorded by Campbell's sunshine instrument during 1882 was 1245, which is more than 40 hours above the average of the 5 preceding years.

"The rainfall in 1882 was 25·2 inches, being very slightly above the average.

"The Westminster clock has maintained its high character, its errors having been under 1s. on 66 per cent. of the days of observation, between 1s. and 2s. on 25 per cent., between 2s. and 3s. on 6 per cent., and between 3s. and 4s. on 3 per cent. The error has never exceeded 4s.

Mr. Christie concludes as follows :—

"The changes suggested in the last Report have been carried out, and will, I trust, tend to increase the efficiency of the Observatory. The restriction of the altazimuth observations of the moon to the semi-lunation from last quarter to first quarter has enabled us to devote more attention to equatoreal observations, though the results hitherto obtained have been somewhat limited through the inadequacy of our instrumental means. The presentation of the Lassell telescope has now removed this difficulty, and when this fine instrument is in working order we may hope to be able to take up with success observations of comets, faint satellites, and other objects of interest. In regard to the spectroscopic observations we have now two observers available, and it may be expected that in the coming year we shall reap the full benefit of the arrangement by which Mr. Nash takes a share in this work.

"In solar photography we have undertaken the measurement and reduction of Indian photographs, supplementing those taken at Greenwich from the commencement of 1882. The Solar Physics Committee propose to undertake the arrears of this work for preceding years.

"In some slight degree the past year has been one of transition and of preparation for future work. Some administrative changes have been made, and the observers have been gaining experience in some new directions; but the regular course of observation and reduction has not been disturbed, and it has been my special endeavour to maintain the standard meridian observations in full vigour—a task in which I have received the hearty cooperation of all the staff.

"In regard to the coming year, I may mention one special work of meteorological reductions which it seems desirable to take in hand. The hourly ordinates of barometer and thermometer registers have been read out and tables of mean values formed for the 20 years of the meteorological reductions, and also year by year since 1877; but there is a gap of three years for the barometer (1874–1876), and of 8 years for the thermometer (1869–1876), for which the photographs have not been discussed. The continuity of the Greenwich series is thus broken, and the results are not available to their full extent. The dis-

cussion which I contemplate for the years in question would probably occupy one computer for a year and a half, involving an outlay of about 70*l*."

ON THE DARK PLANE WHICH IS FORMED OVER A HEATED WIRE IN DUSTY AIR[1]

IN the course of his examination of atmospheric dust as rendered evident by a convergent beam from the electric arc, Prof. Tyndall noticed the formation of streams of dust-free air rising from the summits of moderately heated solid bodies (*Proc. Roy. Inst.*, vol. vi. p. 3, 1870). "To study this effect a platinum wire was stretched across the beam, the two ends of the wire being connected with the two poles of a galvanic battery. To regulate the strength of the current a rheostat was placed in the circuit. Beginning with a feeble current, the temperature of the wire was gradually augmented; but before it reached the heat of ignition, a flat stream of air rose from it, which, when looked at edgeways, appeared darker and sharper than one of the blackest lines of Fraunhofer in the solar spectrum. Right and left of this dark vertical band the floating matter rose upwards, bounding definitely the non-luminous stream of air." . . .

"When the fire is white hot it sends up a band of intense darkness. This, I say, is due to the *destruction* of the floating matter. But even when its temperature does not exceed that of boiling water, the wire produces a dark ascending current. This, I say, is due to the *distribution* of the floating matter. Imagine the wire clasped by the mote-filled air. My idea is that it heats the air and lightens it, without in the same degree lightening the floating matter. The tendency, therefore, is to start a current of clean air through the mote-filled air. Figure the motion of the air all round the wire. Looking at its transverse section, we should see the air at the bottom of the wire bending round it right and left in two branch currents, ascending its sides, and turning to fill the partial vacuum created above the wire. Now as each new supply of air, filled with its motes, comes in contact with the hot wire, the clean air, as just stated, is first started through the inert motes. They are dragged after it, but there is a fringe of cleansed air in advance of the motes. The two purified fringes of the two branch currents unite above the wire, and, keeping the motes that once belonged to them right and left, they form by their union the dark band observed in the experiment. This process is incessant. Always, the moment the mote filled air touches the wire, the distribution is effected, a permanent dark band being thus produced. Could the air and the particles under the wire pass *through* its mass, we should have a vertical current of particles, but no dark band. For here, though the motes would be left behind at starting, they would hotly follow the ascending current, and thus abolish the darkness."

Prof. Frankland (*Proc. Roy. Soc.*, vol. xxv. p. 542), on the other hand, considers that what is proved by the above described observations is that "a very large proportion of the suspended particles in the London atmosphere consists of water and other volatile liquid or solid matter."

Last summer (1881) I repeated and extended Tyndall's beautiful experiment, not feeling satisfied with the explanation of the dark plane given by the discoverer. Too much stress, it appeared to me, is placed upon the relative lightening of the air by heat. The original density is probably not more than about 1/1000th part of that of the particles, and it is difficult to see how a slight further lightening could produce so much effect. In other respects, too, the explanation was not clear to me. At the same time I was not prepared to accept Prof. Frankland's view that the foreign matter is volatilised.

The atmosphere of smoke was confined within a box (of about the size of a cigar-box), three of the vertical sides of which were composed of plates of glass. A beam of sunlight reflected into the darkened room from a heliostat was rendered convergent by a large lens of somewhat long focus, and made to pass in its concentrated condition through the box. The third glass side allowed the observer to see what was going on inside. It could be removed when desired so as to facilitate the introduction of smoke. The advantages of the box are twofold. With its aid much thicker smoke may be used than would be convenient in an open room, and it is more easy to avoid draughts which interfere greatly with the regularity of the phenomena to be observed. Smouldering brown paper was generally used to produce the smoke, but other substances, such as sulphur and phosphorus, have been tried. The experiment was not commenced until the smoke was completely formed and had come nearly to rest. In some respects the most striking results were obtained from a copper blade about ½-inch broad, formed by hammering flat one end of a stout copper rod. The plane of the blade was horizontal, and its length was in the line of sight. The unhammered end of the rod projected from the box, and could be warmed with a spirit-lamp. The dark plane was well developed. At a moderate distance above the blade it is narrow, sometimes so narrow as almost to render necessary a magnifying glass; but below, where it attaches itself to the blade, it widens out to the full width, as shown in the figure.

Whether the heated body be a thin blade or a cylindrical rod, the fluid passes round the obstacle according to the electrical law of flow, the stream-lines in the rear of the obstacle being of the same form as in front of it. This peculiarity of behaviour is due to the origin of the motion being at the obstacle itself, especially at its hinder surface. If a stream be formed by other means, and impinge upon the same obstacle without a difference of temperature, the motion is of a different character altogether, and eddies are formed in the shadow.

The difference of temperature necessary to initiate these motions with this dark plane accompaniment is insignificant. On July 20, 1881, a glass rod, about ¼-inch in diameter, was employed. It was heated in a spirit-lamp, and then inserted in the smoke-box. The dark plane gradually became thinner as the rod cooled, but could be followed with a magnifier for a long time. While it was still quite distinct the experiment was stopped, and on opening the box the glass rod was found to be scarcely warmer than the fingers. It was almost impossible to believe that the smoky matter had been evaporated.

In order to test the matter more closely, smoke was slowly forced through a glass tube heated near the end pretty strongly by a spirit-lamp, and then allowed to emerge into the concentrated sunshine. No distinct attenuation of the smoke could be detected even under this treatment.

It is not necessary to dwell further upon these considerations, as the question may be regarded as settled by a decisive experiment tried a few days later. The glass rod before used was cooled in a mixture of salt and ice, and after wiping was placed in the box. In a short time a dark plane extending *downwards* from the rod, clearly developed itself and persisted for a long while. This result not merely shows that the dark plane is not due to evaporation, but also excludes any explanation depending upon an augmentation in the difference of densities of fluid and foreign matter.

The experiment was varied by using a U-tube through which cooled water could be made to flow. When the water was not very cold the appearances were much the same as with the solid rod; but when by means of salt and ice the tube was cooled still further, a curious complication presented itself. Along the borders of the dark plane the smoke appeared considerably brighter than elsewhere. Sometimes when the flow was not very regular it looked at first as if the dark plane had been replaced by a bright one, but on closer examination the dark plane could be detected inside. There seems no doubt but that the effect is caused by condensation of moisture upon the smoke due to the chilling which the damp air undergoes in passing close to the cold obstacle. Where the fog forms more light is scattered, hence the increased brightness. That the fog should not form within the smoke-free plane itself is what we might expect from the interesting observations of Aitken.

With respect to the cause of the formation of the dark plane, the most natural view would seem to be that the relatively dense particles are thrown outwards by centrifugal force as the mixture flows in curved lines round the obstacle. Even when the fluid is at rest a gradual subsidence must take place under the action of gravity; but this effect could at first only manifest itself at the top where the upper boundary of the gas prevents the

[1] Paper read at the Royal Society, December 21, 1882, by Lord Rayleigh, F.R.S., Professor of Experimental Physics in the University of Cambridge.

entrance of more dust from above. It is known that air in a closed space will gradually free itself from dust, but the observation of a thin dust-free stratum at the top of the vessel is difficult. If we conceive a vessel full of dusty air to be set into rapid rotation, the dust might be expected to pass outwards in all directions from the axis, along which a dust-free line would form itself. I have tried this experiment, but looking along the axis through the glass top of the vessel, I could see no sign of a dark line, so long as the rotation was uniform. When, however, the vessel was stopped, a column of comparatively smoke-free air developed itself along the axis. This I attributed to the formation of an inward flow along the top of the vessel, combined with a downward flow along the axis after the manner described and explained by Prof. James Thomson, so that the purified air had been in intimate proximity with the solid cover. It would almost seem as if this kind of contact was sufficient to purify the air without the aid of centrifugal force.

The experiments made hitherto in order to elucidate this question have given no decisive result. If the thin convex blade already spoken of be held in the smoke-box in a vertical instead of in a horizontal plane, the lines of motion are much less curved, and we might expect to eliminate the influence of centrifugal force. I have not succeeded in this way in getting rid of the dark plane; but since under the magnifier the curvature of the motion was still quite apparent, no absolute conclusion can be drawn.

ON THE MORPHOLOGY OF THE PITCHER OF "CEPHALOTUS FOLLICULARIS"[1]

THE brief, but most interesting, memoir on this subject read by Prof. Alexander Dickson before the Botanical Society of Edinburgh on March 10, 1881, was the first to throw any clear light upon the obscurity which had previously enveloped it. The conclusions at which he arrived seemed to be fully sustained by the facts which he then published; but since there are still botanists who do not fully accept those conclusions, any independent evidence bearing upon the problem of the morphology of these curious pitchers may be worth recording.

The publication of Prof. Dickson's memoir caused me to watch the growth of my plants of Cephalotus with increased interest. From time to time abnormal leaves have made their appearance, which seemed to afford more or less support to the views which the Professor entertained. This spring one of my plants has developed a leaf the growth of which I have watched. When this leaf first became visible it bore no indication of being other than an ordinary leaf of the plant, but its upper surface soon exhibited a somewhat shrivelled appearance, like that of a leaf distorted by the action of Aphides. It soon became evident that this disturbance was but the commencement of the process of pouching described by Prof. Dickson. That which at first appeared to be a mere distortion of the surface of the leaf soon deepened into a considerable depression, which became more considerable day by day until the leaf reached the condition represented in my figures 1, 2, and 3. Fig. 1 represents the upper, 2 the lateral, and 3 the inferior surface of this leaf.

From the beginning of its growth *a* was the unmistakable, somewhat cuspidate apex of the leaf, as it was also the distal end of the prominent ciliated ridge, *b*, the obvious precursor of the middle dorsal wing, which forms so conspicuous a feature of the normal pitcher. It will be seen in Fig. 2 that this ridge only extends downwards to the point *c*, whilst *d* was evidently the fundus of the enlarging pouch, relations which approximate closely to what characterise these portions of the perfect pitcher. On the under surface of the leaf (Fig. 3) we find this middle wing extending downwards from *a*, flanked on either side by a smaller, slightly curved ridge, also ciliated, the two unquestionably representing the lateral wings of the normal organism. It is perfectly clear that the peripheral outlines of the figures 1 and 3 represent the true primary margins of the leaf from the point *a* to the base of the petiole *e*. The upper half of this margin is abundantly ciliated, the hairs becoming more scanty as we approach the lower half of the leaf.

Figs. 1 and 2 show the form of what obviously represents the lid, *f*, of the true pitcher. In its essential features it accords with those figured by Prof. Dickson, who correctly recognised its true homology. As in his Fig. 5, this lid is two-lobed, its central indentation, *g*, separating two triangular lobes. This arrangement corresponds substantially with what exists in the normal pitcher, only in the latter the lobes are large and rounded instead of being small and triangular. The free margin of this rudimentary lid is abundantly ciliated, as in the perfect pitchers.

Thus far my specimen only confirms and illustrates the conclusions arrived at by Prof. Dickson, viz. that the pitcher is merely a depression in the upper surface of the leaf, of which the petiole *e* is identical morphologically with the terete petiole of the true pitcher, whilst the lid, *f*, is an outgrowth of the

FIG. 1.

FIG. 2.

upper surface of the leaf from the proximal margin of that depression.

Prof. Dickson was not able to decide with absolute certainty which part of the matured normal pitcher represented the primary apex of the leaf. In his abnormal specimens, as in mine, that apex coincided with the apex *a* of the middle dorsal wing. As is well known, in the perfect pitcher the entrance into the pitcher is bounded by a thick, involuted, toothed rim, to which the apical point of the dorsal wing is external. The Professor

FIG. 3.

was uncertain whether the apex *a* of the wing coincided with the true apex of the leaf, or whether that apex is hidden in the involuted margin of the pitcher. He inclines, however, towards the former view, and I have the conviction that he is right. The two *ciliated* margins, *a' a'*, of Fig. 1, are obviously the two lateral margins of the anterior portion of the normal leaf, demonstrating clearly that the point *a* is its apex. In the true pitcher these margins have lost their ciliæ, a few prominent teeth being substituted for them, and become thickened at their inner side

[1] By W. C. Williamson, LL.D., F.R.S., Professor of Botany in the Victoria University, Manchester.

by the development of the rounded and ribbed involuted border. It appears clear to me that this thick involuted structure is an outgrowth from the upper surface of the leaf, and which crossed the base of the cuspidate apex, *a*, without materially modifying it; and as it developed in a similar manner round the base of the distal surface of the lid *fg*, it contracted that base so as to reduce the attachment of the lid to the pitcher to very small dimensions. If the explanation is as correct as I believe it to be, the apex *a* of the middle dorsal wing is also the true apex of the leaf, whilst the involuted margin of the pitcher and the whole of its lid are equally outgrowths from its upper surface.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE

OXFORD.—In a Convocation to be held in the Sheldonian Theatre on Wednesday, June 13, at twelve o'clock, it will be proposed to confer the degree of D.C.L. *honoris causâ* upon Lord Rayleigh, M.A., F.R.S., Professor of Experimental Physics and Honorary Fellow of Trinity College, Cambridge, and Sir Frederick A. Abel, K.C.B., F.R.S.

In a Convocation held on June 5 the following decree was submitted to the House:—"That the Curators of the University chest be authorised to expend a sum not exceeding 10,000*l*. in the erection of a laboratory, working-room, and lecture-room for the Waynflete Professor of Physiology, and in providing fixtures, warming apparatus, and gas for the same," which was carried by 88 to 85.

CAMBRIDGE.—The Geological Museum Syndicate recommend the combination of a new chemical laboratory with the Sedgwick Geological Museum, and believe that no better site will be available than the Downing Street frontage. They have asked permission to obtain plans and estimates in accordance with this proposal.

The Special Board for Medicine recommend the combination of the subjects of botany and comparative anatomy, now taken in the 1st and 2nd M.B. respectively, into one—elementary biology, which is to include much less than the two separate subjects. They propose that chemistry and physics in the 1st M.B. may be taken at a distinct period from the elementary biology, if candidates prefer it, and also that human anatomy and physiology in the 2nd M.B. may be taken at a distinct time from pharmacy and pharmaceutical chemistry. They also propose to discontinue classifying candidates, which has only been adopted of late years, and to publish merely alphabetical lists.

The university Local Lectures in populous centres have during the past winter, as usual, included numerous courses on science subjects, including chemistry and electricity, by Messrs. C. M. Thompson and S. L. Hart; Europe in Prehistoric Times, by Mr. J. E. Marr; Geology and Physical Geography, by Mr. W. W. Watts; Physics of the Earth, by Prof. Teall, &c.

LONDON.—On Tuesday afternoon last a large number of the friends of the medical education of women met at the Ladies' Medical College in Brunswick Square at the ceremony of presenting the prizes to the successful students of that institution. Countess Granville presided, and in the course of the proceedings Mr. Stansfeld, M.P., referred to the financial condition of the college as satisfactory. Two gentlemen from India spoke on the recent movement in Bombay to secure qualified medical women for that country, and referred to the immense value of a knowledge of medicine as an adjunct to missionary effort. Mrs. Garrett-Anderson, M.D., as Dean of the College, supplied some statistics of its progress, and Mrs. Fawcett, in proposing a vote of thanks to Countess Granville, dwelt on the assistance which the movement for placing a medical training within reach of women had received from Earl Granville in his capacity as Chancellor of the University of London.

WITH a view to encourage the study of veterinary science, the Lieutenant-Governor of Bengal has resolved to offer two prizes—one of 50*l*. and the other of 20*l*.—for competition by holders of Agricultural Scholarships from Bengal, studying in the Royal Agricultural College, Cirencester.

SCIENTIFIC SERIALS

THE *American Journal of Science*, No. 149, May, 1883.—Observations of the transit of Venus, December 6, 1882, at Princeton, New Jersey, and South Hadley, Massachusetts, by Prof. C. A. Young. Two sets of measurements of the planet's diameter, and some spectroscopic observations were made by the author and Mr. McNeill. During the transit 191 photographs were taken by Prof. Brackett and assistants. Of these 40 were first class, 30 worthless, the rest of all grades of excellence. The planet's atmosphere was seen by all observers at Princeton. But no satellite, spots, or marks were detected upon the planet's disk.—Notes on the occurrence of certain minerals in Amelia County, Virginia, by Wm. F. Fontaine. These have been brought to light during the excavations carried on for some years past for the purpose of obtaining mica. They are chiefly feldspar, beryl, fluorite, columbite, garnet, orthite, microlite, monazite, and helvite.—On the surface limit or thickness of the continental glacier in New Jersey and the adjacent States, by J. C. Smock.—Contributions to the geological chemistry of Yellowstone National Park, by F. Leffmann and W. Beam.—Notes on American earthquakes, with records from June, 1879, to end of December, 1882, by Prof. C. G. Rockwood.—A four years' record of earthquakes in Japan, studied in their relation to the weather and seasons, by Dr. Thos. H. Streets, U.S. Navy. The shocks are tabulated, with remarks on the state of the barometer and temperature. Three charts show the relation between the height of the barometer and the earthquakes.—Observations on the fossils of the metamorphic rocks of Bernardston, Mass., by R. P. Whitfield.—On De Candolle's "Origin of Cultivated Plants," with annotations upon certain American species, by Asa Gray and J. Hammond Trumbull (part ii.).

Annalen der Physik und Chemie, 1883, No. 5.—Experimental researches on the elliptical polarisation of light by reflection from surface-coloured bodies, with ten illustrations, by Julius Merkel.—A new radiometer, described and figured by C. Bauer.—The radiation of rock-salt under various temperatures, by the same author.—On the generation of heat in the absorption of gases by solids and fluids, with illustration, by P. Chappuis.—Some remarks on the action of air condensed on glass surfaces, by W. Voigt.—On the theory of the longitudinal impact of cylindrical rods, by the same author.—Observations on the action of quicksilver drops falling in thermometrical tubes, by Paul Volkmann.—On the galvanic resisting-power of psilomelan, by Hugo Meyer.—Remarks on W. Siemens' theory of luminosity, by W. Hittorf.—On a hitherto unrecorded phenomenon acccompanying electric discharges, with three illustrations, by Heinrich Hertz.—On the action of platinum, palladium, gold, coal, and aluminium in nitro-muriatic acid, by Carl Fromme.—On the dynamometrical method of determining the ohm, by J. Fröhlich.—On the measurement of local variations in terrestrial magnetic horizontal intensity, by F. Kohlrausch.—Researches in the electromagnetic phenomena of rotation, with three illustrations, by Friedrich Koch.—Experiments in connection with the theory of the Nobili-Guébhard rings, by W. Voigt.—Measurement of the diminution of sound in the telephone, by K. Vierordt.—On electric undulatory movements, with illustration, by A. Overbeck.—On the selective absorption of solar energy, with two plates, by S. P. Langley.—Remarks on C. Bohn's treatise on "Absolute Dimensions," by Paul Volkmann.—An account of Foucault's experiment with the pendulum, by A. Schuller.

No. 6.—On the measurement of the refractive relations of coloured fluids, with four illustrations, by C. Christiansen.—On the determination of the power of emission and absorption of heat in bodies, by the same author.—Observations on Norman Lockyer's theory of dissociation, by Hermann W. Vogel.—Researches on the variation of temperature in the pole-plates of a voltameter during the transmission of electric currents, with two illustrations, by E. Edlund.—Carl Fromme's electrical investigations (continued): Experiments on the condensation and absorption of hydrogen by platinum and palladium; *résumé* and further explanation of the results contained in the two previous sections.—Remarks on A. Kundt's treatise on "The Optical Action of Quartz in the Electric Field," by W. C. Röntgen.—On some experiments with static electricity, with numerous illustrations, by V. Dvorák.—Some remarks on the unipolar conduction of solid bodies, by F. Braun.—On the elliptical polarisation of the heat rays reflected by metals, by H. Knoblauch.—On the fluorescence of the vapour of iodine, by E. Lommel.—On the thermodynamic equilibrium of vapour mixtures, by Max Planck.—On some modifications of the pyknometer, by G. W. A. Kahlbaum.—On the selective absorption of solar energy (continued), with fresh observations on the invisible prismatic spectrum, by S. P. Langley.

THE *Beiblätter* to part 4 contains papers on the necessity of introducing certain modifications into the study of mechanics, and eliminating diverse problems from them, by Yvon Villarceau.—On the influence of temperature on manifestations of molecular energy, by A. Millar.—On the inner pressure and energy of superheated vapours, by G. Schmidt.

Journal de Physique Théorique et Appliquée, April, 1883.—Methods for determining the ohm, by Marcel Brillouin.—On the solidification of phosphorus and other substances in superfusion, by M. D. Gernez.—On the theory of colourless curves in double refractive crystals, by J. Macé de Lépinay.—A new hygrometer condensing internally, described and figured by A. Crova.—A new electrocapillary translator, described and figured by E. Debrun.—On the reading of a system of two electrodynamic machines, by A. Potier.

Revue Internationale des Sciences, February, 1883, contains articles:—On the contagiousness of tubercle.—On the Khouds, by Élie Reclus.—On the dangerous properties of finely-divided coal-dust, by Prof. Abel.—On the adulteration of food in Paris, by M. Egasse.—Medical anthropometry from the point of view of aptitude for military service, by M. Jansen.—Proceedings of the Academy of Sciences, Paris.

Journal of the Asiatic Society of Bengal, Vol. li. Part II, No. 4, 1882, contains:—On a new species of Hipparchia from the North-West Himalayas, by Major G. F. L. Marshall.—Notes and drawings of the animals of various Indian land mollusca, by Lieut.-Col. H. H. Godwin-Austin (Pl. 5).—Some further results of sun-thermometer observations, with reference to atmospheric absorption and the supposed variation of solar heat, by H. F. Blanford.

THE *Archives des Sciences Physique et Naturelles* for March contains papers by M. Schneebeli, on the determination of the absolute capacity of some condensers in electromagnetic measurement; by Raoul Gautier, on the great comet of September, 1882; by Dr. Julius Maurer, on the theory of the atmospheric absorption of solar radiation.—M. Casimir de Candolle has an interesting biographical notice of the eminent naturalist Emile Plantamour.

SOCIETIES AND ACADEMIES

LONDON

Royal Society, April 19.—"On the Limiting Thickness of Liquid Films." By A. W. Reinold, M.A., Professor of Physics in the Royal Naval College, Greenwich, and A. W. Rücker, M.A., Professor of Physics in the Yorkshire College, Leeds.

The previous investigations of the authors have shown that the specific electrical resistance of a soap film thicker than 374×10^{-6} mm. is independent of the thickness, and that the composition of films formed of M. Plateau's "liquide glycérique" may be largely altered by the absorption or evaporation of aqueous vapour which attends even slight changes in the temperature or hygrometric state of the air (*Phil. Trans.* Part II. 1881, p. 447).

In the present paper they describe a modified form of the apparatus which they previously employed. The glass case in which the films are produced is surrounded by water, and additional precautions are adopted for maintaining the aqueous vapour within it at the tension proper to the liquid of which the films are formed. These changes have entailed considerable alterations in details, but the main features of the apparatus remain unaltered. The new form, however, possesses the important advantage that the temperature and hygrometric state of the air in contact with the films can be kept perfectly constant during the progress of the experiments. With this apparatus a number of measures have been made of the electrical resistance of films which have thinned sufficiently to show the black of the first order of Newton's rings. To deduce the thickness from the resistance, it is necessary to assume that the specific resistance of the films is the same as that of the liquid in mass. The authors' previous experiments do not enable them to assert the truth of this assumption for such thin films, and it was therefore important to ascertain by an independent method whether it might be taken as approximately true.

For this purpose between fifty and sixty plane films were formed in a glass tube 400 mm. long and 18 mm. in internal diameter. The tube was closed by pieces of plate glass and placed in the path of one of the interfering rays in a Jamin's "interferential refractometer." When the films had become black, a known number were broken by bringing an electromagnet near to the tube and thus moving some sewing needles which had been inclosed along with the films. The mean thickness of the films was deduced from the displacement of the interference "fringes" caused by their rupture.

Two liquids were observed, viz. M. Plateau's "liquide glycérique," and a soap solution containing no glycerine. The following are the means of the various groups of observations:—

Liquid.	Method.	Mean thickness in terms of 10^{-6} mm.
"Liquide glycérique" ...	Electrical... ...	11·9
	Optical	10·7
Soap solution	Electrical... ...	11·7
	Optical	12·1

The agreement between these numbers is sufficiently close to make the fact that they are approximately correct unquestionable, and to prove that the mean thickness of a black film is nearly the same for both liquids.

The electrical observations afford a means of comparing the thicknesses of different black films and observing whether or not the thickness of the black portion of any particular film alters as its area increases. The results obtained in the paper and in a previous preliminary investigation on the same subject (*Proc. Roy. Soc.*, 1877, No. 182, p. 334) are summed up by the authors as follows:—

(1.) Persistent soap films which thin sufficiently to exhibit the black of the first order of Newton's rings invariably display an apparent discontinuity in their thickness at the boundary of the black and coloured portions.

(2.) The whole of the black region, at the time of or very soon after its formation, is of uniform thickness.

(3.) This thickness remains unaltered in any film, whether the coloured parts of the film are thinning or thickening, increasing or diminishing in extent.

(4.) It is different for different films, but no connection has been traced between its magnitude and the time which elapses between the first formation of the film and the first appearance of the black, or between either of these and the time of observation.

(5.) The mean values of this thickness are the same to within a fraction of a millionth of a millimetre, whether the films are plane or cylindrical, in contact with metal or with glass, formed of soap solution alone, or with the addition of more than two-fifths of its volume of glycerine.

(6.) Two totally independent methods of measuring the thickness of the black portions of the films give completely concordant results.

(7.) The mean value of the thickness calculated by giving equal weight to the results of the electrical and optical experiments is $11·6 \times 10^{-6}$ mm. The extreme values formed were $7·2 \times 10^{-6}$ and $14·5 \times 10^{-6}$ mm.

The smaller of these quantities is therefore a limiting thickness to which a soap film in air saturated with the vapour of the liquid from which it is formed rarely attains, and below which none of the films observed by us have thinned.

Linnean Society, May 24.—Anniversary Meeting.—Sir John Lubbock, Bart., president, in the chair.—Mr. R. McLachlan read for the Audit Committee the statement of receipts and payments for the year; 750*l.* had been invested, and a balance at banker's (April 30) remained of 514*l.* 8*s.* 7*d.*—The Secretary (Mr. B. D. Jackson) read his annual Report. Since the last anniversary 11 Fellows and 1 foreign member had died and 11 withdrawn, while 54 new Fellows had been elected. Between purchase, exchange, and donations, 407 volumes and 442 separate parts had been added to the library.—Mr. G. J. Romanes, on behalf of the subscribers, formally handed over the portrait of Charles Darwin, painted by Mr. J. Collier, its exhibition at the Royal Academy last year having then prevented its presentation.—A bust of the late Prof. Louis Agassiz by the American sculptor, Mr. Hiram Power, was handed over by Prof. Allman to the Society as a present from the sculptor's son, Mr. H. Power of Florence.—An engraving from Gainsborough's painting of the old English naturalist, Mr. Thomas Pennant, was presented by Mr. Howard Saunders in the name of Mrs. Alston, as a bequest from her son, the Society's late secretary, Mr. E. R. Alston.—The President then delivered his anniversary address, commenting generally on the events of the past year, with special reference to their bearing upon the Society; in congratulating

the Society on its annual balance-sheet, he reminded the Fellows that, besides investments, the property of the Society might be valued at 25,000*l.*, or a total of 30,000*l.*; he alluded to colonial Fellows and the good work they are doing, incidentally referring to the British Association meeting in Canada in 1884. Reference was also made to the progress of rearrangement of the Biological Collections in the Natural History Museum at South Kensington; this was followed by reports on the various botanical and zoological publications issued at home and abroad during the last twelvemonth. Remarks were made on the stock of the Society's Journals and Transactions, also on the purchase of a portrait of Jacob Bobart (1598–1679), and the President himself presented a valuable portrait of Linnæus painted from life, by the Swedish Magnus Hollman.—A resolution was unanimously accorded by the Society, at the instance of the Chair, to Mr. G. Bentham and Sir J. D. Hooker on the completion of their great work, the "Genera Plantarum."—The scrutineers having examined the ballot, then reported that Mr. Thomas Christy, Mr. H. E. Dresser, Mr. G. Murray, Mr. H. Saunders, and Mr. H. T. Stainton had been elected into the Council in the room of Mr. H. W. Bates, Mr. G. Busk, Mr. C. B. Clarke, Sir John Kirk, and Mr. R. McLachlan, who retired; and for officers, Sir J. Lubbock as president, Mr. Frank Crisp as treasurer, and Mr. B. Daydon Jackson and Mr. G. J. Romanes as secretaries.

Physical Society, May 26.—Prof. Clifton in the chair.—Mr. G. Griffith read a paper on the graphical representation of musical intervals, in which he gave an account of previous attempts to represent musical intervals in a graphical manner, and exhibited an enlargement of a diagram published by Dr. Pole in Sir F. Ouseley's "Treatise on Harmony." In this diagram the musical intervals contained in one octave are represented by the differences between the logarithms of the vibration-numbers forming them. Mr. Griffith proposes to apply this principle to the whole musical scale. Retaining the lines used in ordinary music he inserts a faint line between these at unequal distances to represent the tones and semitones. Several diagrams were exhibited, in which the principle was applied to the representation of intervals to the sequence of the keys in the major diatomic scale, and to actual music. Mr. W. G. Blakely and Dr. Coffin considered that it would be a great help to students to have the method proposed. Mr. Blakely considered that it combined the advantages of the tonic solfa and ordinary notations. Dr. Coffin thought that it might become generally used.—A paper by Dr. J. Fleming on a phenomenon of molecular radiation in incandescent lamps. When the carbon filament in an Edison lamp volatilises, the vapour is condensed on the glass in a cloud. When the copper electrode is volatilised, the copper is likewise deposited, but there is a bare space or line left on the glass in the plane of the filament, forming as it were a shadow of the filament. Dr. Fleming explains this on the supposition that the copper particles are thrown off in straight lines, as in a Crooke's vacuum. This shadow is not noticed in the carbon deposits. Dr. Fleming also remarks that the colour of a thin copper couch is the same as a thin layer of gold in transmitted light.—Mr. W. Baily read a paper on an illustration on the crossing of rays. He took the case of three rays of homogeneous light of the same intensity, and parallel to one plane, and polarised so that the vibrations were also parallel to the plane, and he exhibited and explained diagrams showing the motion which would occur under the circumstances.—Prof. F. Guthrie exhibited one of Chladin's plates bearing a striking resemblance to one of these figures. Mr. Baily thought the analogy might be a real one.—Prof. Clifton described an improvement which he had made in the glass insulating stem he had exhibited to the Society on a former occasion. This stem had a glass cup encircling it, and of a piece with the stem. Sulphuric acid was put into the cup. The new pattern had a hole formed into the bottom of the cup, and the upper part of the stem fitted into this hole like a stopper. It could thus be removed at will and the acid renewed. Prof. Ayrton stated that he had used a similar arrangement for nearly two years, a narrow necked glass bottle taking the place of the cup.—[In the report of the Physical Society for April 28 (p. 47), Mr. H. R. Droop's name was written *Troop*.]

Entomological Society, May 2.—J. W. Dunning, M.A., F.L.S., &c., president, in the chair.—The President said: "You scarcely need to be reminded that we this day complete the fiftieth year of our existence. It was on May 3, 1833, that nine gentlemen—Messrs. Children, J. E. Gray, G. R. Gray, Hope, Horsfield, Rudd, Stephens, Vigors, and Yarrell—met and resolved to found the Entomological Society of London. No time was lost; for on the 22nd of the same month the first general meeting was held at the Thatched House Tavern, the Rev. Wm. Kirby was chosen Honorary President, 103 Members were enrolled, and a Council of thirteen were chosen to complete the organisation of the Society and prepare rules for its government. Rooms were taken at No. 17, Old Bond Street, and on November 4, 1833, under the presidency of Mr. Children, the then Secretary of the Royal Society, a code of by laws was adopted and our first scientific meeting was held. Of the original Members six, and six only, still survive—Prof. C. C. Babington, the Rev. Leonard Jenyns (now Blomefield), Sir Sidney S. Saunders, Mr. W. B. Spence, Mr. G. R. Waterhouse, and Prof. Westwood. Of these Mr. Waterhouse has the additional distinction of having been one of the original Council, and the first Curator of the Society. Our meetings continued to be held at 17, Old Bond Street, from 1833 until 1852, when we removed to No. 12, Bedford Row; during nine sessions commencing in 1866, by the kindness of the Linnean Society, we assembled in Burlington House, but our library remained in Bedford Row. In 1875 the library and place of meeting were again united in this house; and though the building operations now in progress have prevented us from indulging in any celebration of our jubilee, we shall soon be in the enjoyment of improved accommodation, and I hope it may be long before the Society has again to change its quarters. At the present moment we have 33 Subscribers and 205 Ordinary Members, making a total of 238 contributing Members. Three years ago I ventured to express from this chair a hope that we might be able to publish a jubilee list of not less than 300 Members. It is not yet too late. And I appeal to each and all of you, gentlemen, to be active in striving to attain this object. 'The Entomological Society of London is instituted for the improvement and diffusion of entomological science.' From first to last this has been our only object. To bring fellow-workers into friendly communication and facilitate the interchange of ideas, to extract the hidden knowledge of secluded students, to provide a library for consultation, to encourage observation and experiment, and to publish the results for the benefit of all whom they may concern—such is our aim, the very reason of our being. And I venture to assert that the Society has succeeded in its object. If any be inclined to doubt, I refer him to the thirty volumes of our *Transactions*, to the *Record of Proceedings* at our more than 600 meetings, as proof of our activity and of the unfailing ardour with which the Society has now for half a century devoted itself to the diffusion of entomological science. I can only regret that by the irony of fate it has fallen to *my* lot to fill the presidential chair on this occasion, when, of all others, it ought to have been occupied by one of the fathers of British entomology. But you have willed it otherwise, and I will bury my regret; nay, it is already swallowed up in the delight I feel at the commission with which I have been intrusted by the unanimous voice of the Council, and I am sure that the proposition I have now to make will meet with your approval, and be carried by acclamation. I have to suggest that Prof. Westwood be made titular Life-President of the Society. There is no man to whom we as a body owe so much. An Original Member, he has never failed us; during the crucial period of our childhood he was the motive power, the life and soul of the Society; for fourteen consecutive years he was Secretary, and for part of that time he was Curator also. The Council has seldom been complete without him; he has been vice-president times without number, and during six years (1851–52, 72–73, 76–77) he was our president. Whilst he resided in or near London he rarely missed one of our meetings; even Oxford cannot keep him away from us; and there is not a single year from first to last that he has not been a contributor to our *Transactions*. From 1827 to the present time his pen and his pencil have never been idle; his papers are scattered broadcast over the scientific publications of this and other countries. Scientific bodies, both at home and abroad, have delighted to do him honour. I do not propose to abdicate the function with which your kindness has invested me. But if it be your pleasure to adopt the suggestion that has been made, I shall be proud to recognise Prof. Westwood as my titular chief, and to yield the chair to him at any of our scientific meetings when we are favoured with his presence. I know no better way of showing that our constancy is equal to his, and that our gratitude is enduring and lifelong. It is a barren title and an empty honour, but it is all that we as a Society can bestow. He has grown gray in our service, and in recognition of his

services, to us in particular and to our science in general, I ask you to confer upon him a title which will be a standing record of the esteem in which we hold him, and which throughout the evening of his days shall assure him of our affectionate respect." The proposal was carried by acclamation, and Prof. Westwood was declared honorary life-pre ident of the Society.

Anthropological Institute, May 22.—Mr. Hyde Clarke, vice-president, in the chair.—Mr. G. P. Rathbone exhibited and described a collection of ethnological objects from Bolivia. —Major H. W. Feilden read a paper on stone implements from South Africa. The specimens exhibited form part of a collection made by the author in Natal, the Transvaal, and Zululand during the years 1881 and 1882. Out of the large number of worked stones and implements that have passed through the author's hands he had seen scarcely any with water-worn edges. It would appear, therefore, that these implements, chiefly made of comparatively soft materials, must have been used and lost in the immediate vicinity where they are now found, and the large numbers found in certain spots seem to indicate settlements on stations at such spots; moreover, the most prolific spots are generally just those which would be most advantageous for procuring game. On the summit range of the Drakensberg and in its rocky kloofs, where game must always have been scarce, stone implements are scarce, if not altogether absent, whilst on the lower levels of the Newcastle district, which even in the memory of middle-aged colonists swarmed with countless herds of antelope, we find abundant traces of the Stone period. The conclusion at which the author arrived was that the users of the stone implements found in the more recent of the superficial alluviums were not separated from the present day by any great lapse of time. On several occasions crystals of quartz were found in company with stone implements in the alluviums, and the author believed that the Stone age people had carried these crystals either as charms or ornaments. Possibly the Stone age existed for a lengthened term in South Africa, and may resolve itself into Palæolithic and Neolithic periods, but at present we have hardly sufficient data at command to enable us to arrive at definite conclusions.—The Rev. C. T. Price read a paper by the Rev. James Sibree on relics of the sign and gesture language among the Malagasy.

Institution of Civil Engineers, May 22.—Mr. Brunlees, president, in the chair. The first paper read was on the Edinburgh Waterworks, by Mr. Alexander Leslie, M.Inst.C.E.—The second paper read was on the waterworks of Port Elizabeth, South Africa, by Mr. J. G. Gamble, M.A., M.Inst.C.E.—The third paper was on the water-supply of Peterborough, by Mr. John Addy, M.Inst.C.E.

PARIS

Academy of Sciences, May 28.—M. E. Blanchard, president, in the chair.—The following papers were read:—General considerations on scientific methods with special reference to the *a posteriori* method of Newton and the *a priori* of Leibnitz, by M. E. Chevreul. The author concludes that the experimental inductive method, as practised by Newton and his successors, is unquestionably the cause of the progress of the physico-chemical sciences, while the absolute *a priori* method, as conceived by Leibnitz, barred the way to all further progress. While Newton sought the proximate cause in order gradually to ascend to a possible first cause, Leibnitz started from the first cause, which for him was everything. The study of the material world accessible to the senses led, according to the German philosopher, to nothing real, while the spiritual world, without parts or dimensions, as represented by monads, numerical unities endowed from their creation with motion, was the object of pure knowledge, that is, of God Himself.—An account of the meteorological station of Aigoual in the Cevennes, where an observatory for the systematic study of atmospheric phenomena is about to be erected, by F. Perrier.—Remarks on the violet sulphate of iridium in the heated state, due apparently to oxidation, by M. Lecoq de Boisbaudran. —On the physical and chemical constitution of the vine-growing lands treated by the method of submersion in the lower Rhone valley and Languedoc, by M. P. de Gasparin.—Experimental researches on the action of various alcohols applied slowly and continuously to the pig, by MM. Dujardin-Beaumetz and Audigé. The alcohols invariably produced sleep, prostration, lassitude, while absinthe gave rise to phenomena of excitation somewhat analogous to epilepsy. During the experiments, begun in June, 1879, and concluded in July, 1882, some of the animals died from the effects of the alcoholic poison, and others were sacrificed in order to study its action on the vital functions. This was in all cases found to be injurious.—Observations on the great comet of September, 1882, made at the Paris Observatory, by M. G. Bigourdan.—On the relations existing between the covariants and invariants of the binary form of the sixth order, by C. Stephanos.—On the relations existing between solar eclipses and terrestrial magnetism, by P. Denza.—Note on the hydrates of baryta, by H. Lescœur.—Constituents of the Montrond (Loire) mineral water, by M. Terreil.—On some combinations peculiar to the kreatine and kreatinine groups of substances, by E. Duvillier.—On the fermentation of bread-stuffs, by M. Chicandard. —On some features in the structure of the placenta of the rabbit, by M. Laulanié.—On the origin of the follicular cells and of the ovula in Ascidians and other animals, by M. H. Fol. The author considers that these cells are genetically the strict homologues of the spermatoblasts in zoosperms, while the ovula itself corresponds to the polyblast or male ovula of Duval.—On the formation of the cystoliths and their reabsorption in plants, by M. Chareyre.—On the shingle, sand, and mud formations along the beach of geological seas, by M. Stan. Meunier.—Fresh observations on the dimorphism of the foraminifera, with four illustrations, by MM. Munier-Chalmas and Schlumberger.—On a saccharine substance extracted from the lungs and phlegm of consumptive patients, by M. A. G. Pouchet.—On condiments, especially salt and vinegar, studied from the point of view of their influence on the digestion, by C. Husson. The author's experiments confirm the conclusions of Wurtz, Dumas, Béclard, Claude Bernard, and others, that taken moderately these condiments are useful, especially in stimulating the formation of the gastric juice. In excess they render the food more indigestible, and are irritating to the coats of the stomach. The proportion of salt should not exceed 5 or 10 grams to 0·5 kilograms of meat; of acids 1 to 4 per 1000.

THURSDAY, JUNE 14, 1883

THE ECLIPSE OBSERVATIONS

THE following telegrams have been received touching the observations of the total eclipse of the sun on the 6th ult. :—

To the Secretary, Science and Art Department

SAN FRANCISCO, June 12, 8.16 A.M.

Double grating on equatorial indifferent; dense prism on 6-inch equatorial good; integrating Hilger good; red end slit good, red end prismatic camera indifferent, first order blue Rowland bad, second order blue Rowland bad, 4-inch photoheliograph indifferent, small photoheliograph good. Lines obtained mostly hydrogen, prominences almost absent.

Through Reuter's Agency

SAN FRANCISCO, June 12

The solar eclipse on the 6th ult. was very successfully observed by the English, American, and Continental astronomers stationed on Caroline Island, the sky being beautifully clear at the time. The corona extended over a distance of two diameters from the sun. The light during the middle of totality was equal to that of the full moon. Successful observations were made by Dr. Janssen, as well as by Prof. Tacchini, the intra-Mercurial planet Vulcan was not seen by M. Palisa. The D line of the spectrum was seen dark in the corona by Dr. C. S. Hastings. Good photographs of the corona were obtained by the English observers as well as by Dr. Janssen. The English observers were also successful in obtaining photographs of the flash. Good photographs were taken of the coronal spectrum in the blue end. The health of Messrs. Lawrence and Woods, the English observers, is excellent.

Putting these two telegrams together, there is every reason to be contented with the work which has been done by the polyglot band of observers on Caroline Island, for, as is to be gathered from the telegrams, this and not Flint Island was the one selected for the site of the observatories. Certainly the photographic attack has been stronger than it has ever been before; more novelties have been attempted, and more have been successfully achieved, whilst the scale on which the work has been done leaves nothing to be desired. Taking, for instance, the photographs of the corona, although we do not know the precise size to which Dr. Janssen limited himself, we may be certain that among his attempts would be included one to take pictures, giving a dark moon of at least six inches in diameter. That by means of the clockwork-driven photographic plate, the flash, by which term is meant that instantaneous appearance of bright lines at the moment of commencement and end of totality, has been secured, shows us that we have now a method of recording eclipse phenomena which is not likely to be neglected on a future occasion. We may hope in a few days' time to get some further information touching the eye-observations made by Prof. Tacchini and the American observers. Reuter's telegram is strangely silent about them at present, and there is little doubt that they have something far more important to tell us than that the dark line D was seen in the spectrum of the corona, for that was observed as long ago as 1871 by Dr. Jannsen. It would be much to be regretted if observations of the lines visible before and after totality were not attempted, especially as we learn that the photographs are limited to a greater or less extent to the lines of hydrogen.

The following general remarks have already appeared in the *Times* with regard to the results of the observations, and we cannot do better than reproduce them :—

"News from the eclipse party has at length arrived. As we stated in our article, published on the 4th of May, the American ship of war, instead of returning to Callao as was at first anticipated, proceeded to the Sandwich Islands, and there is little doubt that the English party made the voyage thence in one of the Pacific mail steamers.

"A telegram coming through Reuter's Agency informs us generally of the success of the observations. The weather seems to have been everything that could be desired, and although the observations were necessarily made from the lowest possible level, the extension of the corona was quite as great as was expected at this period of *maximum* solar activity. Further, we learn that the light during totality was quite equal in intensity to that of the full moon. This is another indication of the exceptional brightness of the corona, because in this eclipse, which was one of exceptional duration—and that is why such strenuous efforts were made to observe it—the lower and more brilliantly illuminated portions of the sun's atmosphere being more than usually veiled by the dark body of the moon during the middle of totality, the illumination of the air by these portions of the sun was less than is ordinarily the case. Unfortunately, the telegram may be read both ways touching the intra-Mercurial planet observations. We take it, however, to mean that no intra-Mercurial planet was seen by M. Palisa, who would probably give his chief attention to that point. It is satisfactory to learn that good photographs of the corona were obtained both by Dr. Janssen and the English observers. We may expect that the French photographs of the corona will surpass in beauty and detail anything which has yet been secured during eclipse observation. It is good news, too, to learn that for the first time in the history of eclipses the momentary flash of bright lines seen just before the beginning and immediately after the end of totality has been photographed. Reverting for a moment to our previous article, we would remind our readers that this end has been attained by the use of a slowly descending plate actuated by clock-work, which, since the flash has actually been photographed, will give its complete history, and enable us to determine the exact order in which the lines appeared and reappeared before and after totality.

"The telegram sent by the English observers, Messrs. Lawrence and Woods, to the Science and Art Department, supplies further particulars as to the results of the various attempts at recording the history of the eclipse. The first instrument on the official list is a Rutherford grating with 17,000 lines to the inch, which was used in conjunction with an equatorial telescope of six inches aperture. The grating was so arranged that the photographs of the green part of the first order spectrum on the one side and the same part of the second order spectrum on the other side should be attempted. This would give the region near F, one of the chief solar lines in the blue-green parts of the spectrum; but although the photographs were actually obtained, the observers do not seem to be very proud of them.

"The next instrument is a dense prism of 60°, mounted on a six-inch equatorial of very short focus. The object in view in employing a short focus was to

obtain a very small and intensely bright image of the corona, while the use of the prism of 60°, giving as small a dispersion as possible, still allowed a really useful amount to be secured. This instrument succeeded well. We do not know the number of photographs obtained by it, but if the instructions were carried out to the letter, seventeen should have been obtained.

"We come next to the instrument by means of which the photograph of the flash of bright lines to which we have referred was obtained. This on the official list is called the 'integrating Hilger.' It is a spectroscope armed with a collimator of very great focal length and directed merely to the sun's place, no image of the sun or corona, therefore, falling on its slit as is usually the case. The light from all the regions near the sun is mingled together, a photograph of the spectrum of this mixture being the special aim of the instrument. Messrs. Lawrence and Woods are evidently satisfied with the work in this direction, the code word they use indicating that they consider the results to be good ones. The moving plate with which the instrument is fitted was exposed two minutes before, and withdrawn from exposure two seconds after, totality. Knowing, therefore, as we do, that one flash was photographed, we may reasonably hope that this was the case also with the other, and as the instructions were to allow the plate to fall through one inch in eight minutes, we may also expect to get a comparison between the flash before and the flash after totality.

"The slit spectroscope armed with two prisms, which was provided by Captain Abney for the observations made last year in Egypt, was utilised also on this occasion with good results. Only one photograph was looked for from this instrument, one which would be exposed from the beginning until the end of totality.

"The prismatic camera, the instrument on the model of that used first in the eclipse of 1875, in which the corona forms its own slit, for some reason or other, does not appear to have been so successful in this eclipse, although it was tolerably so in that of last year.

"The attempt which has been least successful is that in which Prof. Rowland's concave grating was used as a prismatic camera, similar to that to which we have just referred. It was hoped to obtain a photograph of the blue end, both in the first and in the second order spectrum, but the results obtained are ciphered as bad. Seeing that Dr. Janssen was successful in his attempt to obtain large-scale photographs of the corona, we need not regret so much that our attempt to photograph it on a scale of four inches to the sun's diameter was unsuccessful.

"The small photoheliograph that was employed to such good purpose in Egypt last year has again given excellent results, which will be of the highest importance, as they will have been carefully executed, and the American party have taken no photographs themselves on the present occasion.

"The English observers telegraph that the lines obtained in the spectrum of the corona by these various methods are chiefly those of hydrogen. This, of course, does not apply to the flash we have spoken of. They add that the prominences were almost absent. This is an extremely important fact, because it shows what entire justification there was for the prediction made for the present eclipse after that of 1878, observed in the United States. That eclipse occurred at a *minimum* sunspot period, and the hydrogen lines were then seen only with difficulty, while the continuous spectrum of the corona was more or less brilliant. In the present eclipse the hydrogen lines were well seen with a very brilliant corona, as was anticipated would be the case at a period of sunspot *maximum*. This, perhaps, may explain the apparent absence of the prominences, because practically the lower part of the corona was itself made up of them.

"We have not, of course, any detailed information with regard to the results achieved by the other parties, but when our own two English observers have obtained such a rich harvest we are justified in concluding that the work of the American and French parties has been equally fruitful. In that case, the trouble which has been taken to secure the observation of this eclipse, which took place at a greater distance from home than any previously observed, will have been entirely justified.

"As we have said, the results of the other parties will take some time to reach us, but at least we may be sure of this—that the Americans, with their large experience of eclipses and their trained observers, will have much that is new and important to add to the results which our own English party has achieved."

It will be seen from what we have stated and from the extracts which we have made from the *Times* that the Royal Society and the Solar Physics Committee of the Science and Art Department are to be entirely congratulated on the result of their labours, and there is little doubt that in this, as in former eclipses, not only shall we have a most important explanation and verification of previous observations, but fresh questions will be raised to be included in future programmes. It should also be said that the indifferent success telegraphed in some cases may refer to the number of photographs taken rather than to the quality of some of them. It is not likely, for instance, that some photographs were not obtained of the bright lines before and after totality by means of the Rutherford grating, and if only two have been obtained at different epochs the greatest possible value must be attached to them.

The telegram does not state whether the observers have yet reached San Francisco, but in all probability they have, in which case they may be expected home in three weeks' time.

THE FERNS OF INDIA

Handbook to the Ferns of British India, Ceylon, and the Malay Peninsula. By Col. R. H. Beddome, F.L.S., late Conservator of Forests, Madras. Large 8vo, 500 Pages, with 300 Illustrations. (Calcutta: Thacker and Spink; London: W. Thacker and Co., 1883.)

FOR something like the last thirty years Col. Beddome has made a special study of Indian ferns under very favourable circumstances. Holding as he did till about a year ago the post of Chief Resident Conservator of the forests of the Madras presidency, he was brought into daily contact with them in his official work, and at his home at Ootacamund he formed a large collection of them under cultivation, many of which have never reached England in a living state. About 1860 he commenced his well known series of illustrations of Indian ferns, in continuation of Wight's "Icones," in which the ferns had been entirely neglected. His plates, like Wight's, were in quarto, uncoloured, and were mainly executed by native artists. His "Ferns of Southern India and Ceylon" contains plates of 271 species and varieties, and was issued in parts and finished in 1863. His "Ferns of British India," which was devoted to the species not found in the southern presidency, contains 345 plates and was finished in 1868. In 1876 he published a supplementary part, containing 45 additional plates, thus raising the total number to 660, and a revised general catalogue and summary of genera and species.

Now he has retired from his official position and come home to England, and the present work is the firstfruits of his leisure. It contains in a handy form a full description of all the Indian genera and species, and is illustrated by 300 uncoloured plates, reduced by means of photography from those of his larger books, one full page plate, with analytical details being given for each of the ninety-eight genera he adopts, and the others of smaller size interspersed amongst the letterpress. It is the first special book of portable size and moderate price which has been devoted to Indian ferns, and is in every way deserving of the extensive circulation it is sure to obtain.

India is one of the great fern-centres of the world, and it would not be an extravagant estimate to say that three-quarters of the genera and one-quarter of the whole number of ferns are known to grow within the area covered by the present work, which is precisely the same as that included in the "Flora of British India," by Sir J. D. Hooker, of which three volumes are now completed. Europe is not a rich fern-continent, and most of the European species extend their range to the Western Himalayas. The Malay Islands are very rich in ferns, and a large proportion of the Malayan species extend to the Eastern Himalayas and the mountains of the Peninsula and Ceylon; and there are in India a considerable number of endemic species. Col. Beddome deserves full credit for not making or admitting species upon insufficient grounds, and the number described in the present work does not fall far short of six hundred, all of which are Filices in the restricted sense, the Lycopodiaceæ and Rhizocarps, which would carry up the number a hundred more, not being included.

Ferns are plants that suffer very little in the drying process, and they are generally the first plants to be collected when a new country is explored. But on the other hand they are often far too large in size to be well represented in herbarium specimens, and often so extremely variable in habit, that it is very easy to mistake a mere casual variety for a genuine species. The first naming of Indian ferns on a large scale was in the great herbarium of Indian plants distributed by Wallich; but he gave no descriptions, simply names and numbers and localities, and very often confused together two or three totally different plants under the same number. In the five volumes of his "Species Filicum," the species were worked out and described by Sir William Hooker; and they were worked up again with abridged descriptions in the "Synopsis Filicum," which it fell to my lot to continue after his death. In England the other botanists who had specially attended to Indian ferns were Prof. David Don and Messrs. John Smith and Thomas Moore. So that till within a comparatively recent date no one had written upon Indian ferns who had had any chance of studying them in the field. But now the matter stands upon an entirely different footing. In 1880 Mr. C. B. Clarke, who, after working for five years at Kew on the "Flora Indica," has just returned to India, and who had paid special attention to ferns whilst collecting largely in the Himalayas, published in the first volume of the new botanical series of the *Transactions of the Linnean Society*, a revision of the North Indian species, illustrated by 36 plates; and now Col. Beddome, whose field experience has been mainly gained amongst the mountains of the Peninsula, has worked up the whole series, with a full opportunity of consulting the type-specimens of his predecessors, deposited at Kew, the Linnean Society, and the British Museum.

As regards details of generic and specific limitation of course no two authors who work independently but will vary considerably. In the matter of fern-genera systematists are divided into two parties—one regarding a difference in veining as sufficient in itself to found a genus upon, and the other maintaining substantially intact the time-honoured genera of Swartz and Willdenow, which are founded entirely on characters derived from fructification. Of the first party among modern writers, Presl, Fée, Smith, and Moore are the leading representatives; of the latter Hooker, Mettenius, and Eaton. Upon this matter I differ from Col. Beddome, and the difference amounts to wishing to use different names for perhaps half the species included in his book. Of course what he and Mr. Clarke have written about species-limitation and the distribution of the species through different parts of India will be a great accession to our knowledge; but I am rather amused to see that out of the limited number of new species which Mr. Clarke made he refuses to admit at least half; and that he totally rejects the only material innovation that Mr. Clarke proposed on the classification of our "Synopsis Filicum," the dividing of our *Asplenium umbrosum*, to establish out of part of it a new section of Asplenium, to be called Pseudallantodia, and characterised by a sausage-shaped involucre bursting irregularly. The only points on which I feel inclined to find fault with him are two. The first, that in his key to the genera he puts Hymenophylleæ under Polypodiaceæ, without taking any notice of the difference in the structure of the sporange,—but I see this is noticed in the detailed diagnosis at p. 28. It seems to me that Hymenophylleæ have excellent claims to be regarded as a distinct sub-order. The other point on which I wish to enter a decided objection is to the plan which he follows, or rather want of plan, in citing the authorities for the specific names. When he places a species under a different genus to that under which it was classified by its original describer, he moves backwards and forwards without any uniformity between four different ways of citing the authority. Sometimes he writes "*Gleichenia glauca* (Hook.)" for a plant described by Thunberg as *Polypodium glaucum*, and transferred by Hooker to Gleichenia, which is the plan usually adopted by botanists. But in many other cases he writes "*Botrychium Lunaria* (Linn. under Osmunda)" when the species was described by Linnæus as an Osmunda and transferred by Swartz to Botrychium; or "*Cyrtomium falcatum* (Sw.)" when Swartz called the plant *Aspidium falcatum* and Presl transferred it to Cyrtomium; or even "*Lastrea thelypteris* (Desv.)" for a plant published first by Linnæus as a Polypodium, transferred by Swartz to Aspidium, by Desvaux to Nephrodium, and Presl to Lastrea. And the same uncertainty vitiates his citations of books at the end of his descriptions. His citations refer to the plant, but according to the accepted usage amongst botanists they will be taken, and very often wrongly taken, as referring to the binomial name as used, so that if any one copies synonymy from the book without checking it off he will often find it leads him astray.

J. G. BAKER

OUR BOOK SHELF

Die Weich- und Schaltiere gemeinfasslich Dargestellt. Von Prof. Ed. von Martens. (Leipzig: G. Feytag; Prag: F. Tempsky, 1883.)

"CONCHOLOGY is ris!" was the pithy remark of the lamented Edward Forbes, made in his cheery way about forty years ago, when Mr. James Smith of Jordan Hill directed his attention to the arctic nature of some fossil shells in the Clyde district. Capt. Brown, however, had previously but unconsciously published the same hypothesis, which has been lately confirmed and extended by the discoveries of Messrs. Steele and Scott at Glasgow. Since the above remark was made by Forbes the study of the Mollusca has in a general point of view marvellously increased and become popularised by innumerable publications. We have now no fewer than six periodical works on the subject, English, French, Belgian, German, Italian, and American, besides four most useful manuals in English, French, German, and American. The German and latest manual, now before me, has been written by an experienced conchologist whose father (Georg von Martens) was favourably known to science nearly sixty years ago by his "Reise nach Venedig." The present author may therefore be considered an hereditary naturalist.

The manual of Prof. von Martens differs from that of Dr. Paul Fischer ("Manuel de Conchyliologie") which is in course of publication, as well as from Woodward's "Manual," in its plan and popular mode of treatment, although all these works are equally good. The present treatise on the soft or naked and shelly Mollusks forms a small octavo handbook of 327 pages, and is illustrated by 205 figures. The principal contents of the work are as follows:—

(1) Names and position in zoology; (2) The shell in general; (3) Organic structure of the Mollusca; (4) Cephalopods; (5) Univalve shells, Nudibranchs, Heteropoda, Pteropoda, and Solenoconchia; (6) Bivalves; (7) Habitat and geographical distribution; (8) Enemies and use of the Mollusca. The illustrations are excellent; they are not arranged in plates, as in the manuals of Woodward and Fischer, but are dispersed throughout the work in their appropriate places by way of explanation. This is in some respects an improvement, although it causes an unnecessary repetition of the same figures. For instance *Margaritana margaritifera* (why not *Unio margaritifer?*) is figured three times in pp. 196, 221, and 311.

The curious varieties or monstrosities of *Planorbis multiformis*, a tertiary shell from Steinheim, are well shown in Fig. 128. I am very glad to see that the author is by no means addicted to an excessive multiplication of genera and species, which is the normal failing of so many Continental conchologists, especially in the land and freshwater shells. In the Pteropoda he has rightly adopted Pallas's generic name *Clione* (1767-1774) for *C. borealis*, instead of Müller's name *Clio* (1776), which Fischer has used in the reverse sense. *Clio* of Linné (founded on Browne's genus and Jamaican species) is wrongly represented in the manuals of Fischer and von Martens by *Cleodora* of Lamarck. As no review or notice of any book is regarded as complete or satisfactory without a dash of criticism, however slight, I would venture to suggest a few corrigenda for the next edition. It is impossible to distinguish *Helix hortensis* from *H. nemoralis*, except as a variety, the former being more northern and the latter more southern in geographical distribution. *Hyalæa* of Lamarck (1810) ought to be *Cavolina* of Gioeni (1783) and Abildgaard (1791), not of Bruguière (1792); *Loripes* is not a synonym of *Lucina*, but a distinct genus, and *Sphærium* is a much older name than *Cyclas*. But I make these few remarks more for the consideration of the author than from any pretence on my part to be a judge. I can heartily and conscientiously recommend this manual not only to the scientific but to the ordinary class of readers. J. GWYN JEFFREYS

Notes on Qualitative Analysis, Concise and Explanatory. By H. G. H. Fenton. (Cambridge University Press, 1883.)

THESE are ordinary tables of reactions of the "more common metals and acids," and also of some of the "more common organic bodies." The organic bodies include carbohydrates and a few alkaloids.

It is very strange that the farce of common and rare elements is still maintained in nearly all the tables and books on qualitative analysis. Surely such elements as titanium and tungsten and molybdenum and selenium or lithium are common enough, at any rate in laboratories, to have a place given to them in analysis books, not to mention thallium, glucinum, and cerium, which do occur in minerals, to the no small mystification of the poor student crammed up with tables of analyses of "common metals." There are rather too many empty pages in these "Notes," and the size is inconveniently large for working with on a laboratory bench.

Practical Chemistry, with Notes and Questions on Theoretical Chemistry. By William Ripper, Science Master, Sheffield Board School. (London: Isbister, 1883.)

THESE notes and questions, mostly questions, have been, as the author explains, compiled to prepare students and teachers for the examinations of the Science and Art Department. It is to be regretted that such books are required, for although, as the author states in his preface, the arrangement may have been very successful in "passing" students, it is questionable whether the information and knowledge obtained are of such a nature as to be valuable afterwards. The book is well adapted for its purpose, that of cramming.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts, No notice is taken of anonymous communications.*

[*The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to insure the appearance even of communications containing interesting and novel facts.*]

The Matter of Space

WILL you permit me to express my thanks to Prof. Herschel for his flattering review of my paper on "The Matter of Space," in NATURE, vol. xxvii. p. 349? It is certainly gratifying to find that the views which I deduced from the ordinary relations of moving matter are confirmed by the results of mathematical analysis, and it is a source of satisfaction to me to have called forth such a studied and thorough treatment of the subject as Prof. Herschel has given it. I cannot but retain my view of the unity in character of all substance, to which he objects, yet in that respect our opinions diverge but slightly, since I replace ether with excessively disintegrated matter, and he considers the particles of ponderable matter to consist of aggregates of ethereal substance. An ether whose condensation yields particled matter answers all the requirements of unity of substance.

As the subject is under discussion, there are some further points in the motor relations of particles which it may be well to indicate. It is highly improbable that the molecules of matter, even if it be in the state of a rare gas, wander at will, constantly changing their relations of position to other molecules. More probably there is very little independent change of place, each molecule being usually held as a close prisoner in a nest of surrounding molecules. The grouping of molecules may be changed by the action of external agencies, but a new molecular equilibrium tends to be quickly established. Such seems the general tendency of nature. If some of the molecules in a mass of substance have an independent motion, friction soon disseminates that motion, and brings them into harmonious conformity with

their fellows. This we know to be the case with all moving masses of matter. Their independent motion is gradually overcome by friction, and their motion brought into accordance with that of surrounding masses. The same principle applies to molecules. Friction, or molecular impact, its equivalent, must quickly reduce their discordant movements, and bring all the molecules of a mass into harmonious motor relations.

Molecules are related to their fellows in three distinct methods, those of the solid, the liquid, and the gas. We can only conjecture the character of these relations. In the solid there is perhaps no impact of molecules under normal conditions. Each molecule may lie in the centre of a nest of attractions, within which it describes a vibratory movement, without coming into contact with any of the similarly moving molecules that surround it. In the gas attraction also acts, but not vigorously enough to restrain the moving molecule, and cause vibration. Here, then, impact is incessant. Yet the molecule can seldom escape from its nest. It is driven backwards on all sides, and held captive within a contracted space. A certain harmony must arise between the motions of these gas molecules under conditions of equalised temperature, which must tend to produce an equal resistance to escape in every direction, and to confine each within a fixed space in relation to those surrounding. Such is not the case when in one gas a volume of a different gas is set free. The molecules, moving with different speeds, cannot harmonise in their impacts. The molecules of the second gas find open spaces in the net of the first, and rapidly disseminate themselves. But the probability continues that in every homogeneous gas, at a fixed temperature, there is little or no free excursion of molecules. In the liquid there are also probably harmonious relations of molecular motion. The character of this motion we do not know. It is possibly a rotation around general centres of gravity. However that be, each molecule must, under homogeneous conditions, move within fixed limits.

If such be the case, each molecule of a homogeneous mass occupies a fixed field, from which it cannot of itself escape, and whose boundaries it cannot change. These boundaries are absolutely fixed by two energies. One of these is the momentum of the molecule, by which it drives back those surrounding it. The other is the pressure bearing upon the mass of which it forms a part. This pressure is usually very great, so that the space occupied by each molecule is very minute, and its change of direction is necessarily very frequent. The pressure constitutes a tension, to which every molecule is subjected, and each has a normal rate of vibration, in accordance with this tension. Of course the weight of the molecule is a constant element in determining its vibratory pitch, which is therefore dependent upon the fixed element of weight and the varying element of pressure.

Such may be the condition of equilibrium of all material molecules, whatever their state of aggregation, namely, the confinement of each molecule within a limited field, within which it incessantly moves, but from which it cannot escape. And to this condition of absolute localisation of every particle all matter tends to come, according to the theory of dissipation of energy. But as nature now exists there are opposing influences which constantly overcome the tendency to localisation. One of these is the attraction of gravitation, which causes independent motion both in masses and in molecules. The other is the heterogeneity of momentum of molecules, or what is usually known as inequality of temperature.

So far as the first of these is concerned, matter is now nearly in equilibrium. The spheres are yet contracting, under the influence of gravity, but this contraction is so gradual as not to materially affect the relations of molecules. Their mutual localisation is but slightly disturbed by this cause. The inequality of temperature is a more vigorous disturbing cause. To this are chiefly due those transfers of energy through space, and of matter through other matter to which all life and activity must be ascribed. The inequality here referred to, as mentioned in my former paper, is not of absolute heat contents, but of temperature, which is a very different thing, since density affects the heat-containing powers of matter, and two masses of different density may be equal in temperature while very unlike in heat contents.

The accepted view of radiation is that there is everywhere an unceasing outward transfer of molecular motion, that each molecule constantly yields and constantly receives radiant heat, changing in temperature when these transfers are unequal, but not when they are equal. This seems to me an incorrect view of the subject. If two masses of matter of equal temperature be in contact there can be no radiation at all, instead of a double radiation. For no molecule can transfer any of its energy to others. If two molecules of equal momentum come into contact, neither can lose nor gain momentum. The momentum of each remains the same after as before the contact, and there cannot properly be said to have been a mutual transfer of energies. The only change that takes place is a change of direction of motion, and in this respect the change in the one case balances that in the other.

Thus properly we can speak of a transfer of motor energy only when the momentums of the molecules differ, and in this case the transfer is from the most to the least vigorous only. Heat is yielded outwardly, but not cold. This transfer is continually taking place, since the temperature of matter is very far from a state of equilibrium. The transfer takes place in two methods. One of these is through direct collision. The other is through vibratory impulse. We must consider these in succession.

Collision constantly takes place between the molecules of gases. It takes place also in solids and liquids when by any cause their molecular equilibrium is disturbed. The result of a transfer of energy in this manner is what we may call an impact radiation. Motion cannot lose or gain speed or change in direction except through the influence of counteracting energies. Thus every impact radiation must run directly outward until overcome by opposing energies of equal vigour. It is transferred from particle to particle, its speed changing in accordance with the weight of the particles, but its momentum continuing unchanged. Such impulses are constantly travelling in all directions. They are very frequently checked by equal opposite impulses, and thus become local motion of molecules. This is the ever-acting equilibriating tendency.

The other mode of molecular transfer is that supposed to be through exchange of vibrations—the radiation of light and heat. This transfer presents two relations. One is that of speed. This depends not on the speed of the motion, as in impact transfer, but on the tension of the conveying particles. As their tension increases, the radiant wave is conveyed more rapidly. As it diminishes, the wave travels more slowly. It is quite possible, indeed, that the waves of light may move with a different speed in interastral space from their known rapidity in the ether of the solar system, since ether may not be everywhere in the same state of tension. If so, certain astronomical conceptions would be affected. This equal speed of radiant transfer, whatever the rapidity of the vibration, indicates that radiance differs essentially from impact transfer. In fact, there is no special necessity in their character that transverse vibrations should be transferred. They may cease with any particle, and continue to exist as continuous vibration of that particle, or the energy of the vibration be yielded to it as direct motion. If in this case the particle move more vigorously than those surrounding, the vibratory transfer will be replaced by impact transfer.

This cessation of radiant transfer is constantly taking place. Every wave of light and heat that comes to the earth's surface is partly converted into local heat, partly transmitted through transparent substances and partly repelled from the surfaces of substances. Thus radiant transfer seems to be rather an accident than a necessity of matter, since the energy thus transferred can be immediately exchanged into local energy, without the agency of equal opposing energy, as in impact transfer. Whether the wave shall travel onwards, be absorbed, or be repelled, appears to depend on the tension of the substance which it affects. Each molecule of every mass has its normal pitch of vibration, in accordance with its weight and tension. If the radiant vibration be in complete accord with that pitch it will be retained as local heat vibration. If in imperfect accord it will be partly held. If discordant it will be transferred or repelled. In the latter case it probably follows the easiest channel. Although the direction of the ray is readily changed, yet probably it has a special vigour of movement in the direct channel. Other things being equal, it would follow the direct in preference to the reflected course. Therefore in cases of reflection there must be a resistance in the molecules of the reflecting substance which makes it easier for the wave to change its direction than to force itself on these molecules. This change of direction in the wave, however, is not a change in the direction of motion. The vibration continues in its original plane. It can only be changed from this plane by special influences within transparent substances, in which the wave vibrations, while acting upon the molecules of the substance, are in some way distorted by their interaction with the normal molecular motions.

There are two other methods of transfer of molecular motion to which brief allusion may be made. One of these is the electric transfer. The character of this we do not know, but we have reason to believe that it is vibratory, and that it bears certain analogies to light vibration. The other method is heat conduction. This is a transfer of energy by exchange of normal vibrations. It takes the place in solids of the impact transfer in gases. The molecule of the solid, when possessed of excess motive energy, cannot yield it to others by impact, and must therefore do so by a drag upon these others through the ties of attraction. This is the slowest of all modes of transfer of energy. For its proper action it is necessary that the substance should be homogeneous, and the vibrations of its molecules normal. The instant the tension changes, either by connection of unlike substances or a condensing twist in a homogeneous substance, the mode of transfer changes. The heat vibration of the molecule is offered to another of different pitch, which refuses to receive it as normal vibration, and at once the rapid electric transfer manifests itself. Normal heat vibration is thus converted into thermoelectricity.

Their brief review may help to give some idea of the relations between molecules. In their state of normal equilibrium, which they seek to regain after every excursion, they possess no independence of movement, but are rigidly confined within fixed limits. They may change place in common with all the molecules of the mass to which they belong, but not independently. Vigorous disturbing influences may break up the molecular grouping, but immediately a new stable grouping is assumed. The incessant molecular disturbances which occur do not usually cause a change of grouping. These consist of vibratory transmissions of energy, and of transfers of motion through impact of molecules, and their effect is but the production of momentary variations in the direction and vigour of the motion of the affected molecule. To the influences of this character above mentioned may be added those of the vibrations of sound, of magnetic energy, and of chemical affinity. The latter alone produces any marked variations of molecular grouping.

Philadelphia, U.S. CHARLES MORRIS

On the Morphology of the Pitcher of "Cephalotus follicularis"

I OBSERVE that the last sentence but one of my brief notice of Cephalotus, which appeared in NATURE last week, is calculated to convey an erroneous impression. The lid *g* of Fig. 1 is seen to be a conical structure with a relatively broad base and a narrower indented apex. In the matured pitcher the free portion of the lid is much broader than its more contracted base; and the developed and involuted margin referred to extends round the mouth of the pitcher *until it reaches that base, but does not cross it*, as by an oversight on my part my words imply.

Fallowfield, Manchester, June 8 W. C. WILLIAMSON

A Large Meteor

THE meteor seen by Mr. Hall of Shoreham (NATURE, vol. xxviii. p. 126) was also observed by Mr. James Cullen of the Stonyhurst Observatory. Its path, as seen from here, was from S.E. by E. to N.E. by E. (true), traversing an arc of about 70°. Its altitude was not more than from 12° to 15° above the horizon. It travelled exceedingly slowly, was visible for about 20 seconds, and was first seen at 10.30 p.m. G.M.T. Its size was that of the full moon, white in colour, and with a tail 10° to 12° in length. It burst into a shower of small pieces before it disappeared, presenting exactly the appearance described by your correspondent.

Owing to the twilight and to the haze which hung about the horizon, its position could not be referred to the stars, the only star visible being α Aquilæ, near which the meteor passed. From the compass bearings and altitude given above its approximate path was from Æ 18h. 50m., $\delta - 2°$, to Æ 22h. 35m., $\delta + 25°$.

Stonyhurst Observatory S. J. PERRY

YOUR correspondent, A. Hall, in your issue of June 7, records the appearance of a large meteor seen by him at Shoreham, Kent, on Sunday evening, June 3, at 10.40. I recorded the same meteor in the *Newcastle Daily Journal* as follows:—

"*An Enormous Meteor.*—Mr. Barkas informs us that on Sunday evening, June 3, at 10.40, an enormous meteor of great brilliancy moved slowly across the heavens from south to north, at an elevation of 30 degrees, and nearly horizontally. The colour was bright white, the apparent length 5 degrees; it had the form of an artist's brush; and the handle broke into many fragments. The head suddenly disappeared. This meteor was seen at Newcastle, Wreckington, and Cullercoats, and it would be interesting to know in what position it was observed at points far south of Northumberland."

Your correspondent does not say whether he saw it towards the south or north, nor does he state its elevation above the horizon. It would be interesting to know its apparent elevation at places north of Kent and south of Northumberland.

Newcastle-on-Tyne, June 8 T. P. BARKAS

Intelligence in Animals

IN NATURE (vol. xxviii. p. 82) is a letter headed "Intelligence in a Dog," which certainly shows that a power of reflection is sometimes possessed by the canine species far beyond what one ordinarily observes in them. Perhaps the following anecdote will interest some of your readers, in which it will be seen that the common crow of India exhibits (occasionally at least) an equal amount of a quality superior to what is usually styled *instinct* in animals.

In the summer of 1878, when I and a friend were travelling in the Himalayas, we marched from Dharmsala to Simla, passing through the native states of Mundi, Suket, Bilaspur, and Erki. One day, when we were about half way between Suket and Bilaspur, we rested two or three hours under the shadow of a rock whence there issued a spring of water most welcome to us thirsty and somewhat weary travellers. We drank our fill and threw ourselves down upon the ground. After we had been there a short time an old crow and its half-grown young one came also to slake their thirst. I happened to have a small piece of a stale chuppati (or unleavened bread which the natives eat) in my pocket, and I threw it to them; the old bird examined it, turned it over, and then called her young one to come and partake of it. The latter did his best to obey his parent, but the morsel was so hard and dry he could not manage to eat it, and said so in his own bird language. The old bird then as plainly replied "try again," which he did most obediently, but with no better success. The old bird then took up the rejected piece and deliberately placed it in one of the little streams formed by the water of the spring (perhaps about six feet beneath where I was lying); she then hopped off, followed by her young one, and here comes the most curious part of the story: in about a quarter of an hour or so both birds returned to this spot, the old one with her beak pointed to the piece of chuppati, which by that time had been rendered soft by the action of the water, and by signs and sounds seemed plainly to tell her young one, "There now, the food is soft; eat it, and no more nonsense." This the young bird immediately did.

Copenhagen, June 8 COSMOPOLITAN

MY big black Newfoundland retriever, "Faust," has a chivalrous habit of taking smaller and weaker dogs under his protection, and about two years ago he constituted himself champion of a wretched little thoroughbred mongrel whom we called the "Pauper," because it lived on charity in the garden opposite our house. "Faust" goes out marketing with the housekeeper, and as he has a passion for bread the baker's children always give him a stale roll. One day, for fun, they gave him two, which he picked up with some difficulty and then left the shop, followed by some of the children, one a lad of sixteen. "Faust" walked along the side of the garden railing till he met his pauper friend, to whom he gave one roll, and then ate the other himself, waving his tail vigorously in evident satisfaction. A neighbour of ours has a kitchen cat who was taken in out of charity himself, and who has several times brought in famishing friends for a meal. NELLIE MACLAGAN

Edinburgh, June 11

EASTERN ASIA AT THE FISHERIES EXHIBITION

THE sections of the Fisheries Exhibition devoted to China, Japan, and the British settlements and protected native states in the Malay Peninsula, are in some respects disappointing. The interest and beauty of the Chinese section are indeed unsurpassed; but the other

sections fall far below what might have been anticipated. At the Fisheries Exhibition in Berlin three years ago, Japan was excellently represented; and when we recollect that fish forms one of the principal—probably next to rice and millet, *the* principal—staples of Japanese food, that the fishing-grounds extend from the most northern Kuriles almost within the Arctic circle, through various zones down to the most southern islands of the Loochoo archipelago, where they approach the sub-tropical regions, and that the primitive methods of catching and preserving fish of more than one race are now daily practised in various parts of this chain of islands, known as the Japanese Empire, it will be seen what scope the Japanese authorities had to make their section of much practical and scientific interest. At Berlin their section did possess such interest, and the collection formed for exhibition there has, we believe, been made the nucleus for a domestic and permanent Fisheries Exhibition in Tokio. Failing the time or funds necessary to make a representative collection for London this year, it was open to the Japanese Government to take a single portion of their vast fishing-grounds—such as Yezo, or the Inland Sea, or the Loochoo Archipelago—and represent that only. This has been done by China with marked success. As it is, Japan is represented in the small space allotted to her by specimens of the fish tinned at the Government canning establishments at Sapporo in Yezo, and by a stall full of pictures on silk, lacquer, &c., of fish and fishing. These latter are all marked, "For sale at the close of the Exhibition." Doubtless the Japanese authorities had good reasons of their own for thus limiting their participation in the present Exhibition; still it is permissible to express regret that they did not add, as they undoubtedly could have done, more to its value and interest.

In the Malay States and the Straits Settlements fish is not such a staple of food as in Japan, and they are on the whole fairly represented. The curious Malay method of catching fish by constructing long and labyrinthine bamboo and cane fences, wide at the beginning and narrowing towards the end, where the fisherman's hut is placed aloft, is represented by two or three models. These long fences, sometimes stretching far out to sea, are familiar objects to every traveller in the Straits. They are protected by stringent local ordinances, and woe betide the unskilful shipmaster who runs his vessel through them.

The Chinese section, viewed from a popular standpoint, is certainly a success. No pains appear to have been spared to make it representative of the Celestial Empire in its decoration. The Chinese ambassador himself has contributed two scrolls in large characters containing verses of poetry. To the staff of the Imperial Customs under Sir Robert Hart—foremost in all that is for the welfare and good name of China—belongs the credit of this section. It would of course be impossible to represent in a single foreign contribution the fisheries of China, extending over more than 2000 miles of coast line, as well as many thousands of miles of rivers and canals, and accordingly it was decided to represent thoroughly one portion of the coast. At Berlin the Ningpo fisheries were so represented, and for this year, Swatow, a treaty port on a large estuary a little to the north of Canton, was selected. The nets, boats, lines, traps, and other implements used in fishing here, the dresses of the fishermen at various seasons, models of their huts, and a scientific classification of the fish caught in this district, form the bulk of the Chinese exhibits. In addition to Swatow, an attempt has been made also to represent Ichang, a port on the Yang-tsze, situated about 1000 miles from the sea, as well as the fisheries of South Formosa and the neighbouring islands. The collections were evidently made and catalogued in China and arranged here by experienced hands. The special catalogue published by the order of Sir Robert Hart forms a complete descriptive guide to the whole, and is most interesting and instructive. Speaking generally, it may be said that the observer is most struck in this section with the extraordinary ingenuity displayed in utilising the most ordinary and unpromising objects for the purpose of fishing. Thus in Swatow they employ a boat drawing a few inches of water, with the rail nearly level with the surface. A narrow plank fixed along one side is painted white, and the light of the moon falling on it causes the fish to mistake it for water. They jump over the plank into the boat, where they get entangled in moss or grass. At Ichang, a wild animal such as the otter is trained, not to catch fish, but to frighten them into the net; while at Ningpo, cormorants are regularly and systematically trained to fish. These and many other devices shown at the Exhibition mark the Chinese as the most ingenious and accomplished fishermen in the world. A large collection of corals, of crustaceans, mollusks, and other fish will attract the scientific observer, who will be much assisted in his examination by the special catalogue before mentioned.

NOTE ON THE INFLUENCE OF HIGH TEMPERATURE ON THE ELECTRICAL RESISTANCE OF THE HUMAN BODY

THE experiments which I have now for some years been carrying out as to the various forms of medical electricity have begun to furnish trustworthy results. Some of these, with the help of De Kilner, were incorporated in a paper read before the Society of Telegraph Engineers on March 9, 1882. We there stated that at present "we are hardly in a position to say how far the resistance of the body varies in health; but in disease it can be fairly stated that it sometimes diminishes and sometimes augments." Of this fact we gave illustrations.

It had often occurred to me that the temperature of the human body very probably influences its resistance; and some experiments had been made with a view of testing the amount of such influence. But in pathological researches it is often difficult to find a case not open to exception, and it is frequently necessary to wait a considerable time before, in the impossibility of experiment, accident presents one possessing the necessary conditions. Such a case I have now met with, and it is worth while to place it on record, if only to enable other observers to prosecute this line of investigation.

The patient is a young and intelligent gunsmith aged twenty-two. He had rheumatic fever severely twelve years ago, which, as is usual in young subjects, has left permanent heart disease behind it. This did not, however, prevent his following his trade until the beginning of April in the present year. He then began to suffer from morning rigors, occurring at first at the interval of from seven to ten days, but, since Easter, daily. He came into my ward in St. Thomas's Hospital on April 28. It is not necessary to detail the medical history of the case in a scientific periodical; it will be sufficient to state that about 8.30 a.m. he was in the habit of suffering from severe attacks not unlike those of ague, in the course of which the temperature rapidly rose to 105° F. In the afternoon it sank to the normal human temperature of 98° or 99° F. The cause of this remarkable symptom is still somewhat obscure; it has completely resisted the action of quinine and other antiperiodics, as well as salicylic acid, aconite, and other approved lowerers of temperature. It is probably due to ulcerative endocarditis slowly advancing. The most remarkable part of the case is that it causes the patient no suffering or inconvenience whatever. His mind is clear, and, except the feeling of chilliness during the period of heat, he makes no complaint. He is able to take interest in the determinations which I proceed to give.

It occurred to me that this unusual range of daily tem-

perature (7 F.) afforded the opportunity I had long been seeking. But it was some time before I could arrange suitable apparatus for its examination. A hospital ward is an awkward place for Wheatstone's bridge and delicate galvanometers. Moreover I had before found that from the peculiar conditions of the human body, the testing current, to produce accurate results, requires to be frequently reversed, for fear of opposition currents of polarisation. I am glad to see a confirmation of this observation in a verbal communication of Prof. Rosenthal to the Physiological Society of Berlin on April 13.

It was partly to overcome this difficulty that I devised, at Mr. Preece's suggestion, a dynamometer for alternating currents, of which the general arrangement was described in NATURE some time ago. It was also brought before the Physical Society at their June meeting in Oxford. Although severely criticised by some members of that learned body, it works extremely well, and may be, I hope, an addition to medico-electrical appliances. For the purpose of the present experiment I found that an ordinarily sensitive galvanometer, considerably damped by air-resistance, was sufficient, since by the zero methods of balancing, it is only necessary just to see the deflection before commutating; when balance is obtained, commutation has no effect on the needle of the bridge.

It would require more space than could probably be here afforded to give all details of the experiments, which, moreover, by the courtesy of Capt. Douglas Galton, I hope to bring before the British Association of this autumn. But a brief summary of results is as follows:—

On June 5 I reached the ward at 9.40 a.m. The rigor had begun at 8.30 and was beginning to decline; I had time, however, for the following determinations:—

9.40	R. 4140 ohms.
9.55	,, 3470 ,,
10.10	,, 2900 ,,

These measurements were taken with a very small E.M.F. of about 9 volts. On June 9 I succeeded in reaching the ward during the beginning of the rigor, and took the following measurements, this time with corresponding temperatures:—

10.30 a.m.	Temp. 102°·4 ...	R. 4550
10.40 ,, ...	,, 104°·2 ...	,, 4630
10.50 ,, ...	,, 104°·2 ...	,, 4930

At this point the rigor, temperature, and resistance began to descend. I visited the patient again at

2·15 p.m.	Temp. 103° ...	R. 2300

The apparatus in these observations was left untouched, so as to prevent any accidental change. The measurement was made with a double E.M.F. to those preceding, namely, 18 volts. I determined on each occasion the resistance of the leads and terminals, which I found to be on each occasion 2 ohms.

I cannot help thinking that the difference, which is as nearly as possible twice the smaller amount, is too great to be accounted for by any instrumental error, and that the human body, in spite of its large amount of liquid constituents, follows a similar thermal law of resistance to that influencing solid conductors, though in a very much higher ratio.

Only one other point requires comment, namely, the mode of making contact between the body and the testing apparatus. Prof. Rosenthal in the communication quoted above draws attention to the high insulating powers of the epidermis. In the above experiment I passed the current through the two legs, from one foot to the other, in alternate directions. The feet were previously soaked in salt and water; two large pans containing about a quart of brine each were then placed under the feet, and in each was immersed a plate of copper five inches square connected with the bridge by stout cables. I have found in other experiments that after half an hour the resistance ceases to decrease, and in this experiment it actually increased to the amount of 480 ohms. The whole foot was immersed, its sole resting directly on the copper plate. I have two other methods of making contact in use. The first consists of rubbing the skin with the oleate of mercury; which to the diffusion power of oleic acid adds the conductivity of its base, and then immersing the part in metallic mercury. The other consists of inserting small silver claw-forceps, known to surgeons as "serrefines," through the epidermis into the tissue below. This is rather painful, but not more so than I find medical students eager in the pursuit of knowledge can and will easily undergo.

W. H. STONE

THE AMBER FLORA [1]

THIS is the first volume of a work on the flora of the amber-bearing formations of East Prussia, and is devoted exclusively to Coniferæ. The introduction contains a sketch of the geological history of the order, and among much that is of interest we find an estimate that the existing Coniferæ occupy an area of about 3,000,000 square miles (500,000 German). The described fossil species are now almost as numerous as the living (400 to 450), though a revision might reduce their number by one-half. The colossal dimensions of some of the living Coniferæ are familiar to most, but it is not generally known how nearly these are rivalled by fossil species. Examples are given, as of a stem of *Cupressinoxylon ponderosum*, broken at both ends and 200 feet long, and another 12 to 14 feet across; a stem of Araucarites, 25 feet in circumference, and a silicified stem from California, 33 feet round the butt.

A considerable portion of the work is occupied with a minute and splendidly illustrated inquiry into and description of the microscopic structure of the tissue of existing and fossil Coniferæ, especially with regard to their resin-secreting organs. Goeppert claims to have originated this study forty years ago, and is certainly the chief authority in it. The result of his work shows that the Abietineæ, or fir tribe, have almost alone contributed the amber, and that at least six species produced it, the chief being close allies of the Common Spruce and the American *Pinus strobus*. These possess three separate sets of resin-producing organs chiefly situated in the cambium layers, which are in the form of cells and ducts running in both horizontal and vertical directions, and appearing at a very early stage of growth. Some Pines are liable to frost-cracks, and into these the resin collects and thence exudes, keeping the wound from healing and furnishing a perpetual supply. Very few specimens of amberwood preserve the bark layers with the resiniferous organs, but sufficient is seen to prove that these in no way differed from those of the Abietineæ at the present day, especially of the Spruce.

The most important section of the work probably is the research into the microscopic structure of the wood, which is, however, of an extremely technical nature. Five separate species of *Pinus* are recognised by their wood, and a very rare and doubtful wood-structure is referred to the Taxineæ.

More interesting perhaps to the general reader are the descriptions of fragments of foliage and fructification inclosed in the amber. Insignificant as the figured specimens appear, they are yet in so marvellous a state of preservation that their texture and microscopic structure, and even the glaucous colouring of the under sides of some of the leaves are visible. Twenty species are determined, with a tendency, it is pleasing to find, rather to curtail than to multiply the number previously described. They have been studied with extraordinary care, and the results are consequently unusually satisfactory.

[1] "Die Flora des Bernsteins." R. Goeppert and A. Menge, Naturforschenden Gesellschaft in Danzig. 4to, 1883.

The ABIETINEÆ are represented by 2 *Pines* of the *Tæda* and 2 of the *Pinaster* section, and by 2 *Firs*. It is impossible, with the material, to more than guess at the affinities of the fossil with the existing species in such an immense tribe, but 3 are compared with American, and 1 with a European species. The presence of 2 species of the *Parasol Fir* of Japan is of especial interest, if the appearance of a double midrib on the back of the leaf is a reliable character, but a doubt seems to be expressed in the altered termination of the name, "*Sciadopites*." Nearly all the rest are CUPRESSINEÆ, and many are represented by catkins and foliage. The *Widdringtonias*, a section of *Callitris* confined to the Cape and Madagascar, are represented by 2 species. The almost ubiquitous Tertiary *Libocedrus salicornioides*, allied to the Chilian Incense Cedar, is indisputably present, even its glaucous colour being preserved. Two *Thuyas* are indistinguishable from the Chinese and the American Arbor-Vitæ, and a more doubtful form is nearly related to the *Thuyopsis dolabrata* of Japan. A male catkin exactly resembling that of the Red Cedar of Virginia (from which pencils are made) represents the Junipers, and this extraordinary assemblage is completed by the presence of the common European *Cupressus*. The TAXODIEÆ, again, are represented by *Sequoia Langsdorfii*, a widespread and somewhat northern Tertiary Conifer, closely allied to the Californian Red Wood; *Taxodium distichum*, the Deciduous Swamp or Bald Cypress of Virginia, and the well-known Tertiary, *Glyptostrobus*, all but indistinguishable from the living Chinese species. The last described is an American type of *Ephedra*, or Jointed Fir.

A group of Coniferæ must therefore have existed in Europe, almost on one spot, comprising representatives from nearly every Geographical Province. There were present such magnificent representatives of the Californian Coniferæ as the Red Wood, the Sugar Pine, the Douglas Spruce, the scarcely less majestic Bald Cypress, Red Cedar, Thyua, and *Pinus rigida* of more eastern States, the Chilian Incense Cedar, the Parasol Fir, the Arbor-Vitæ, the *Glyptostrobus*, and the *Thuyopsis* of the Eastern Coasts of Asia, the Scotch Fir, the Spruce and the Cypress of Europe, and the Callitris of Southern Africa. Based on the careful research of a man who has made Coniferæ his especial study for fifty years, these determinations have a value which the haphazard methods of so many workers in Fossil Botany do not possess. The causes which led to the dispersion and extinction in Europe, in such relatively recent times, of so considerable a group of Coniferæ would be interesting to tracc out.

The similarity between the Amber Flora and the overlying Brown-coal Flora, described by Heer, lead to the inference that its age must be Middle Miocene. The deposits are uniformly sand, clay, and loam, in which are imbedded partly rolled stones of various kinds and sizes. The whole belongs to a vast and widely spread amber-bearing "diluvial formation" which stretches from the confines of the White Sea into Holland. The richest deposits are situated along a strip of coast between Memel and Dantzic, but the real home of amber has been supposed to lie in the bed of the Baltic between Bornholm and the mainland. It rests upon Cretaceous rocks, and consists chiefly of their debris, forming a peculiar mixture known as "blaue-Erde," which appears to exist throughout the Province of Samland at a depth of 80 to 100 feet, and to contain an almost inexhaustible supply of amber. The authors wish to correct the name to "blau-grün," to distinguish it from the blue earth which accompanies the brown coal in Silesia and elsewhere. Immense quantities of amber are washed out to sea from the coast, or brought down by rivulets and cast up again during storms or in certain winds. The expectations that amber-bearing beds of equal richness would be found at greater depths farther from the sea have not been realised, and these already priceless and apparently inexhaustible coast-deposits have thereby acquired an enhanced importance. It seems probable that the amber-beds of the North Sea belong to the same formation, and that these may even have been continuous to the east coast of Great Britain.

Though the greatest quantity of amber is found on the coast, the largest pieces, 6·5 and 9·5 kilos., were met with inland. It is never found in paying quantities at a greater depth than 4 to 6 feet, and chiefly in the "diluvial beds" with rolled fragments of brown coal, wood, and stones. It is rare in the brown-coal formation, and even when met with is almost confined to the Upper blue and plastic clays. The quantity, however, seems to be inexhaustible, for the rich and celebrated blue-earth of Samland extends along the coast for 60 miles, and possesses a breadth of about 12 miles and an average thickness of 10 feet. Runge estimates that each cubic foot contains $\frac{1}{13}$ lb. of amber, which gives a total of some 9,600,000,000 lbs. The actual yield at present is 200,000 to 300,000 lbs. per annum, or at least five times the quantity estimated to be cast up by the waves of the Baltic on this coast, so that it appears, at the present rate of quarrying, there is a supply for some 30,000 years to come. A good deal of amber, it must be remembered, is cast up on other Baltic shores and along the North Sea.

In an inquiry as to the probable extent of Pine forests that would be required to produce such a bulk of amber, the authors take the Norway Spruce (*Pinus abies*, Linn.) for the purpose of comparison. Estimating that the full age of the species is 120 years, sixty to seventy of which are resin-producing, they conclude that 6000 lbs. per acre would be the product of each generation, and therefore that the Baltic Sea, with its area of 6370 German miles, might yield, if covered with Norway Spruce, 8,408,400,000 lbs., or about an equivalent to the quantity contained in the 20 German square miles of the Samland "blue-earth" referred to above. It thus appears that if this amber in it had been produced on the spot, some 300 generations would have been required to furnish it, but it is of course far more probable that it has been collected together in its present position by the action of water. These estimates being founded on a species relatively poor in resin, even notoriously less resinous than *Pinus austriaca* and other existing species, it is likely that the amber yield was in excess.

The Amber Flora presents a group of cryptogams comprising 20 Fungi, 12 lichens, and about as many mosses—plants hardly represented in any other Tertiary Flora. It is united to other Miocene Floras, not only by its Coniferæ, but by the widely-spread *Cinnamonum polymorphum*. It contains 42 species of Conifers, Cupuliferæ, Betuleæ, Salicineæ, &c., a species of Hakea, in all 27 Monopetalæ and 12 Polypetalæ, including such rarely preserved orders as Scrophulariaceæ, Primulaceæ, Caprifoliaceæ, and Loranthaceæ, the gatherings from forest, meadow, and fen. These are to be described in a forthcoming work. The Coniferæ are, however, of chiefest interest, more especially as, while resembling the resinous species of the present day, their secretions differed so essentially in quality as to have left a product unknown in any other geological age.

J. STARKIE GARDNER

THE STORY OF A BOULDER

THE Warwickshire papers report a curious open-air service held on Sunday last at Stockton, near Rugby, to "consecrate" a large granite boulder which has been inscribed and railed in at the expense of the villagers. It lies on a bed of concrete in the centre of the little place, protected by a handsome iron railing; a few square inches are polished to show the grain; an inscription records that it was brought from Mount Sorrel, a distance

of sixty miles, by an iceberg or a glacier in the great Ice Age; and the ground around it is to be inclosed, turfed, planted, and set with rustic seats. A fine day, and the novel proceeding, drew a large and attentive crowd; a short, bright service was conducted with the aid of an unusually good village choir; and the big stone set up by Joshua at Shechem formed the text for a sermon intended to stamp the boulder as a religious no less than a scientific monument.

This charming little idyll is the closing chapter in a story which might claim to share the title made historic by a great geologist. Five years ago the present rector, coming to Stockton, found the boulder lying in a ditch, into which it had been rolled from its inconvenient position by the roadside. A hazy clerical belief that it was "Druidic" had saved it from complete destruction; but it was the cockshy of all the children, bonfires were lighted on it occasionally, and it lay at the mercy of every field club which might come hammering that way. Large, glaciated, and of granite, it was clearly worth preserving. The new rector told its probable history from the pulpit, and the village mind was roused. Reports came in of other big stones far and near, some of which were also of glacial origin; the quarrymen in the adjoining lime-works, digging down to a smaller piece of granite and some beautifully striated blocks of sandstone, protected instead of breaking them; and by following up the hint thus given, a fine bed of boulder clay was uncovered, shown to Dr. Crosskey, and inserted in the Boulder Committee Report of the British Association. The fame of the great stone spread; visitors came to see it; the Stocktonians, who had through frequent lectures learnt its scientific value, became proud of their "Pibble" and of their ability to instruct their neighbours; the subscription point was reached, and money found to move and rail in the treasure; the surrounding villages finally emptied themselves to attend the consecration service, and Stockton is at this moment, like douce Davie Deans, "as uplifted as a midden-cock on pattens."

The moral of the story is twofold. First: what has been done in Stockton ought to be done in scores of other villages. This boulder was the first link in a chain of evidence, lengthening ever since, in favour of a new and pregnant probability, the current of an ice-sheet from the Charnwood Forest heights across the table-land of South Warwickshire. In countless corners more lie similar monuments, unknown and doomed, which, if thus preserved and studied, would afford the keys to like problems in geology. And secondly: the clergy ought to do it. Our country parsons are, if they could be educated to see it, the natural discoverers and conservators of local relics; with the opportunities they have and the attainments they ought to possess, they might in their mere leisure write such a scientific history of England as no country has yet possessed. Let them read the delightful chapter in *Le Maudit*, which paints the Curé Julio in his Pyrenean parish, and in order that they may be qualified to imitate him, let the bishops be wise in their generation, and exact a knowledge of some branch of natural history from every candidate for Orders.

REPORT OF THE PARIS OBSERVATORY FOR THE YEAR 1882

WE have received from Admiral Mouchez, the Director of the Paris Observatory, the report on the state of that Observatory for the past year, and as we recently made reference to the state of our own Greenwich Observatory on the occasion of the visitation which took place at the beginning of the present month, we think it may interest our readers if we make a few extracts from this report of Admiral Mouchez.

The report opens with a complaint that the service of the Observatory has been very considerably deranged by the preparations for the transit of Venus. Not only did the various members of the expedition attend at the Observatory in order to be trained either in photography or in the use of the artificial transit, but no less than five of the *personnel* of the Observatory themselves took part in the work. At the same time, says Admiral Mouchez, the past year may take rank with any of its predecessors when the increased work of the Observatory is taken into account, for during this time an extension of ground has taken place, the equatorial coudé has been installed, and several underground chambers have been constructed for the purpose of studying magnetism and terrestrial physics generally. Curiously enough, one of the grounds on which the addition of magnetical studies to the work of the Observatory is urged is, that the cloudy skies of Paris so frequently interrupt the purely astronomical observations, that, without some such work as it is now proposed to add, the observers would frequently have little to do.

Among the purely astronomical work of the Observatory which has been going on for the last four years is that of the revision of Lalande's catalogue of stars, numbering 40,000. Concerning this work, we are informed that the General Catalogue, which will form eight volumes in quarto, is well in hand, and it is hoped that two volumes will be published each year, or at all events four volumes during the next three years. To assist in the construction of the catalogue, 110,000 meridian observations have been made during the last four years.

The employment of ordinary equatorials in an observatory, remarks Admiral Mouchez, necessitates a continual change of position of the observer, he being compelled to follow the movement of the eyepiece into positions which are often inconvenient and fatiguing, whilst the heavy dome of the observatory has also to be constantly rotated to follow the motion of the telescope. In order to obviate the necessity for this, M. Lœwy conceived the idea of adapting to the equatorial the system of "lunette brisée," employed first in England, and afterwards to a greater extent in Germany, especially in small transit instruments.

The new coudé equatorial may be thus described:—The polar axis of the instrument is supported at its extremities on two pillars like a meridian instrument. Round this axis the telescope turns, forming a right angle at the lower support. By means of a mirror placed at the summit of this angle the light is reflected along the pierced axis, at the end of which the eyepiece or the micrometer is placed. Under these conditions, with the telescope at rest, the equatorial stars pass across the observer's field of view. But of course the telescope must not be limited to the observation of equatorial stars. In order to secure the observation of other stars, a mirror free to rotate is placed before the object-glass and connected with the declination circle. The inclination of this mirror may be changed so as to throw the light coming from a star of any declination into the tube. This arrangement therefore permits the observer to explore every part of the heavens without quitting his position at one end of the polar axis. The telescope may, practically, by a rotation of this axis, be directed towards any part of the celestial equator, whilst a star of any declination may be made to throw its light down the broken telescope by means of the external mirror. It might be imagined that in this latter case the double reflection would result in the loss of a good deal of light, but we read that the preliminary experiments have shown that this is not the case, and that the polish and figure of the mirrors are very satisfactory. They are silvered, and of course can be easily repolished. We should add that this instrument, now one of the actualities of the Observatory, is due to the liberality of Mr. Bischoffsheim.

With regard to more strictly physical observations, those who have made their complaint respecting the

recent weather in England will perhaps find a grain of consolation in the statement that M. Thollon, who comes every summer to work in connection with this part of the Observatory, spent his whole summer there last year without being able to make a single observation. M. Egoroff, Professor of Physics at Warsaw, was, we learn, occupied during the months of July and August, as in preceding years, with the spectroscopic study of atmospheric absorption, working with a beam of electric light sent from Mont-Valérien to the Observatory.

Most of our readers are aware that the French Government has, as we think wisely, determined to separate the special meteorological investigations from the astronomical work of the Observatory. In consequence of this decision, Admiral Mouchez is now making meteorological observations of possibly a still higher value, with the special object of determining the different corrections, such as for refraction, to be applied to the astronomical observations.

The magnetical observatory which is now being completed will evidently be one of the first order. Six subterranean chambers of constant temperature have been built under the best possible conditions of isolation and stability. An outer wall of nearly 2 m. thickness incloses a rectangular space 40 m. in length, and 14 m. wide, completely impervious to moisture. The observing chambers, of which there are four of 5 m. by 4 m., and two of 6 m. by 5 m., are constructed in this space, being isolated from its walls by passages 2 m. wide. The walls of the observing chambers themselves are 80 centimetres thick; they communicate with each other by doors 1½ m. wide, and have a height of 3·65 m. The vaulted roof, 1 m. thick, is covered by earth to the thickness of 2 m., whilst grass and plants protect the soil from the direct rays of the sun, and from frost. The observing chambers can either be lighted by gas or by reflection from without.

Advantage has been taken of the existence of these chambers by placing in them the clocks from which the time is distributed throughout Paris, but in spite of all precautions it is unfortunately discovered that the chambers are not altogether free from minor trepidations resulting from the traffic of the streets. It is proposed therefore to place the apparatus for the study of the vertical and slow movements of the soil to a gallery in the Catacombs 27 m. below the surface. This apparatus has been constructed and is ready for use.

Among the meteorological work to be done with the object to which we have previously referred is included a series of observations from a captive balloon. This is of such a size that with ordinary gas in calm weather it can take self-registering barometers, thermometers, and hygrometers up to a height of 500 m., and with pure hydrogen it can ascend to a height of 800 m. It has been found by experiment that the balloon cannot be well managed if the air has a velocity greater than 4 m. or 5 m. per second; but this is not regarded as being inconvenient, because it is during complete calm that those great and frequent inversions of the law of decrease of temperature which most sensibly interfere with astronomical refraction, manifest themselves.

Simultaneous observations will be made on the meridian of the Observatory of Paris, north at the Observatory of Montmartre, and south at the Observatory of Montsouris.

The construction of the great refractor of 16 m. focal length with its dome of 20 m. in diameter is going on steadily. The object-glass worked by M. Martin is already finished, and the ground on which the Observatory is to be built is now prepared. There are some interesting details in the report touching the dome, the dimensions of which we learn will be the same as that of the Panthéon, and the largest ever attempted.

In insisting upon such a dome turning with ease, it must not be forgotten that it would be useless to construct one of such dimensions, unless steps were taken to prevent the ill effects which would arise from any displacement or deformation of the soil on which the Observatory is to be erected, or the walls of the Observatory itself. The arrangement which is to be adopted in the construction of this dome is that proposed by M. Eiffel. In order to reduce to a minimum the resistance due to friction on circular rollers, M. Eiffel proposes to float the dome by means of a circular caisson plunged in a receptacle of the same form, filled with a liquid which will not freeze, such as an aqueous solution of chloride of magnesium. An experiment made with a small model gave hopes of the most satisfactory results with this arrangement. There is much originality in the idea, and at the Paris Observatory more than anywhere else perhaps it is necessary that some such arrangement as this should be adopted, for it must not be forgotten that the Observatory is situated over the Catacombs, one result of which has been that for many years the pillars of the meridian circle erected in the gardens have gradually inclined towards the east in consequence of the displacement of the soil. If the same thing were to happen to the Observatory for the great equatorial, there is little doubt that before many years were over the dome would be quite immovable, whereas with Eiffel's floating arrangement, whatever be the change in level within season due to such a cause as we have named, the dome would still turn.

Another point which is engaging the attention of the Director is the erection of an astronomical observatory on the Pic du Midi, at a height of 2859 m. At this elevation, according to General de Nansouty, it is easy to read at night by the light of the stars alone, and fifteen or sixteen Pleiades are visible to the naked eye. It is indeed time that the importance of the possibility of observations at great heights received a fuller recognition. When the astronomical party were in the Rocky Mountains in 1878, to observe the eclipse of the sun there, three American observers had no difficulty in detecting the satellites of Jupiter every night with the naked eye. Nothing could show better the purity and transparency of the air than this, and to establish these facts is to establish also the necessity for utilising them. It is intended that any astronomer who wishes to make any special researches may take advantage of this Pic du Midi Observatory. At the same time, however, astronomers will be sent from the Paris Observatory to profit by the clear skies of the south at those times when the climate of Paris reduces the number of possible observations in the Observatory itself. It is pointed out that not only the science of astronomy, but physics, chemistry, and physiology, will probably derive great benefit from the institution of such an observatory as this.

NOTES

The Royal Society Soirée last Wednesday was as successful as usual, though the absence of the president, Mr. Spottiswoode, through illness, was to be regretted. From inquiries last night we are glad to learn that Mr. Spottiswoode, who is suffering from Roman fever, is going on very well.

The candidates selected by the Council of the Royal Society, whose names we gave in Nature, vol. xxvii. p. 614, were elected last Thursday.

Dr. Michael Foster has, in accordance with unanimous expectation, been elected to the newly established Professorship of Physiology in the University of Cambridge; and Dr. Alexander Macalister, F.R.S., Professor of Comparative Anatomy and Zoology in the University of Dublin, has been elected to the Professorship of Anatomy, vacant by the resignation of Prof. Humphry.

It will gratify our readers to learn that Her Majesty has subscribed 50*l.* and the Prince of Wales 26*l.* 5*s.* to the fund now being raised by the Scottish Meteorological Society for the establishment of a Meteorological Observatory on the top of Ben Nevis. At a meeting of the Council of the Society on Saturday last, we understand that plans and specifications and offers from several contractors for making a road from Fort William to the top of Ben Nevis were submitted, and it was resolved to commence the making of the road at once; Mr. Sydney Mitchell, architect, was instructed to make arrangements for the completion of the work within two months.

Prof. Morris has presented to University College, London, his valuable geological library.

The following subjects have been settled for conferences at the Fisheries Exhibition; the authors whose names are given have consented to read papers. Many gentlemen have consented to act in this capacity, but the complete list is not yet ready:—British Fisheries and Fishermen, by H.R.H. the Duke of Edinburgh; the Fisheries of the United States, by Prof. Brown Goode; the Fisheries of the Dominion; the Fisheries of other Countries (Commissioners for Sweden, Norway, Netherlands, China, &c., have promised to take part in these conferences); Herring Fisheries, by Mr. R. W. Duff, M.P.; Pilchard and Mackerel Fisheries, by Mr. J. Cornish; Salmon and Salmon Fisheries; Fresh Water Fisheries (including Trout), by Mr. Francis Francis; Seal Fisheries, by Capt. Temple; Oyster Culture and Fisheries, by Prof. Hubrecht; Mollusks, Mussels, Whelks, &c., used for Food or Bait, by Mr. Chas. Harding; Line Fishing, by Mr. C. M. Murdahl; Trawling; the Application of Steam Power to the Fishing Industry; Principles of Fishery Legislation, by the Right Hon. G. Shaw Lefevre, M.P.; Fish Culture and Acclimatisation of Fishes, by Sir James Maitland; Fish as Food, by Sir Henry Thompson; Fish Transport and Fish Markets, by His Excellency Spencer Walpole; Food of Fishes, by Dr. F. Day; Storm Warnings, by Mr. R. H. Scott; Fish Diseases, by Prof. Huxley; Economic Condition of Fishermen, by Prof. Leone Levi; Protection of Life of Fishermen; Scientific Results of the Exhibition, by Prof. Ray Lankester.

The Committee appointed by the French Parliament to consider the pension to M. Pasteur, have agreed to recommend its increase from 12,000 francs to 25,000, with reversion to the widow and children.

Prof. Lenz is about to organise, with the aid of the Russian Geographical Society, a series of observations on terrestrial currents along four lines of Russian telegraphs—Moscow to Kazan and to Kharkoff, and Tiflis to Rostoff and Baku. The necessary instruments are ordered, and the observations will begin as soon as these are ready. These observations were highly recommended, as is known, by the International Polar Committee at its Hamburg meeting, in connection with the magnetic observations of the circumpolar stations, as well as by the Electrical Congress at Paris. Germany has already begun these observations, whilst Austria, Sweden, and Finland are about to start them.

As the Russian Meteorological stations on Novaya Zemlya and at the mouth of the Lena were unable to begin regular magnetic observations on September 1, 1882, and their observations during the first months probably will not have the desired degree of accuracy, the Meteorological Committee of the Russian Geographical Society has applied for grants of money to continue these observations for one year more. Two new meteorological stations have been opened at Obdorsk and at Mezen, in order to connect the Novaya Zemlya observations with those of Central Russia.

On the 5th inst. the Emperor of Austria inaugurated the new Vienna Observatory, on the Turken Schanze, in the northern outskirts of the town. The new building took nine years to construct, and during that time the present director went all over Europe and America in order to study the fitting-up of the best observatories. The result is that the Vienna Observatory is probably one of the most complete in existence. For an account of the great telescope, constructed by Grubb of Dublin, see Nature, vol. xxiv. p. 11.

A competition has been opened by the Genevan Society of Physics and Natural History for the best unpublished monograph on a genus or family of plants. The MSS. may be in Latin, French, German (in Roman writing), English, or Italian, and should be sent to Prof. Alph. de Candolle, Cour St. Pierre, 3, Geneva, before October 1, 1884. Members of the Society are not admitted to the competition. The prize is 500 francs.

M. Marcel Deprez, the author of the experiments on the transmission of force to a distance, has offered himself as a candidate for the place in the Academy of Sciences vacated by the death of M. Bresse, in the section of Mechanics.

There was an interesting gathering at Newnham, Cambridge, on Saturday, to celebrate the success of the College for Women, started there some years ago, and to honour its first and as yet only Principal, Miss Clough, by presenting her portrait to the institution. The progress which has been made in the higher education of women since Newnham was founded is striking. Though only a few years ago the attempt was barely tolerated by the University authorities, now the students are all but nominally attached to the University, and there can be no doubt that ere very long they will obtain all that the friends of these institutions desire. Miss Clough deserved all the honour paid her on Saturday, for mainly to her courage, intelligence, and tact has the wonderful success of Newnham been due.

Apropos of the education of women and of the callings for which they are suited, it is a remarkable fact that the recently opened Brooklyn Bridge, of which we have heard so much as one of the greatest triumphs of engineering, owes its existence partly to the genius of a woman. Mrs. Washington Roebling, the wife of the great engineer who was intrusted with the construction of the Brooklyn Bridge, has been chief of the engineering staff ever since her husband first fell ill. When he was disabled and could not proceed with his great work, Mrs. Roebling began to study engineering, and her success was such that in a short time she was able to take her husband's place, and the enormous structure which Americans not incorrectly call "one of the most conspicuous marvels of the nineteenth century" was completed under her direction. The honour of being the first to drive across the new bridge was well earned by Mrs. Roebling, and the peculiar share which she had taken in its construction was rightly held to justify a disregard of the old superstition which dooms to ill luck the structure over which a woman has been the first to cross.

Prof. A. H. Keane has been elected a Corresponding Member of the Anthropological Society of Washington.

The fifth International Congress of Americanists will be held at Copenhagen, August 21–24. King Christian will be "Protector" of the Congress, while Prince Frederick Christian will be Honorary President. Prof. Worsaae is President of the Committee of Organisation. The subjects to be discussed cover a wide field, including history and geology, archæology, anthropology and ethnography, linguistics and palæography.

The Duke of Westminster has intimated to the Council of the National Smoke Abatement Institution that he purposes to contribute 500*l.* to the Smoke Abatement Fund recently opened.

WE learn from the Spanish papers that the Mining Exhibition now open at Madrid, is a great success. However incomplete, it still represents to a certain degree the present state of this wide branch of n tional welfare of Spain, and probably will give an impulse to the further development of geology, which is one of the most popular sciences with the Spanish *savants*.

THIRTY-TWO schemes were examined by the jury for the erection of a statue to Christopher Columbus at Barcelona. The most accredited opinion in Spanish artistic circles is, however, that none of them corresponds to the greatness of the event of the discovery of a new continent, which it has to commemorate. The statue will be erected on the seashore, facing the port of Barcelona.

A WRITER in the *Times* on the present Czar of Russia and his two predecessors refers to some improvements which have been made during the present reign. "The most hopeful of all recent signs in Russia," he says, "has been the entire cessation of the ecclesiastical censorship that was formerly exercised over scientific writings. The censors used to be attached to the Universities; many of them were nomine s of the higher clergy; and books that were considered unorthodox were never licensed by them unless the author paid fees which deprived him of all profit in his work. This, at least, was generally the case, and if an author evaded payment it could only be through the patronage of some very powerful man. M. Delyanoff has allayed much irritation among Russian *savants* and given a valuable stimulus to University education by limiting the jurisdiction of the censors to political works. So we shall hear no more of books being suppressed—as one was by Count Tolstoi—for inquiring too minutely into miracles alleged to have been wrought by bones of saints drawn from the catacombs of Kieff and sold by the clergy at high prices."

WE have received the sixteenth volume of the *Memoirs of the Society of Naturalists at the Kharkoff University*. It is mostly occupied by a long paper by A. W. Guroff, on the geology of the provinces of Kharkoff and Ekaterinoslav, being a valuable addition to the former work by Prof. Levakovsky, "On the Cretaceous and subsequent Formations," and to the works of MM. Borisyak, Briot, Klemm, and many others. The author describes at length the crystalline rocks of the rapids of the Dnieper, and gives a map of their extension, as well as a classification of this complicated series. He then mentions the littoral formations of the coal-basin of the Don, as well as the coal-measures of the Kalmius, and dwells at some length on the Bakhmut depression, describing the different stages of its Permian deposits. As to the much-discussed question of the upper members of this formation, which are considered by several Russian geologists to belong to the Trias, he is inclined too to consider them as intermediary between the Permian and the Jura, as they contain remains of the *Posidonomya* (*Estheria*) *minuta* and the *Equisetum arenaceum*, which both characterise the same formation on the Volga. The Jurassic deposits which unite the Jura of the Don with that of Kieff, as also the Rhetic group of the Donets, are then dealt with, and a complete list of the Donets Jurassic fauna is given. The Donets Jura proves to be more like the Jura of middle Europe than that of middle Russia. The Tertiary deposits of Kharkoff (the *Spondylus* beds) seem to belong to the Eocene formation, which is covered with sand and sandstone of the Miocene period. The other papers of the same volume are a supplementary list of 200 Diptera of Kharkoff, by W. A. Yaroshevsky, bringing their number up to 908 species; and a note on the parasites of the *Stauronotus vastator*.

THE researches as to the invertebrate fauna of the Black Sea, which were made from 1833 to 1863 by Rathke, Nordmann, Kessler, and Wagner, which researches had brought only to forty the number of species of crustaceans discovered in the Black Sea, have contributed towards spreading the idea as to the remarkable poverty of this fauna. This opinion was rapidly overthrown by the more recent researches of MM. Czerniawsky, Markusen, and Bobretsky, who discovered in the space of a few years no less than 130 new species of crustaceans in the Black Sea, and brought, in 1869, the total number of crustacean species discovered there up to 160. The subsequent dredgings of MM. Krichaguin, Grebnitsky, and Czerniawsky added to the number seventy-six species more, and this last explorer even affirmed in one of his memoirs that the crustacean fauna of a single bay of the Black Sea—the Bay of Yalta—is richer than that of the whole of the Belgian coast. The opinions, however, as to the kinship of the Black Sea fauna with the faunas of the neighbouring seas are still divided. MM. Markusen and Grebnitsky maintained that it is closely akin to that of the seas of the north, and proved it by the presence of such crustaceans as are not met with in the Mediterranean (various species of *Mysis* and representatives of the groups of the *Cumacea*, *Bathyporeia*, *Niphargus*, *Padocerus*, and *Siphonœcetes*), but are common in the seas of the north. They pointed out also the circumstance that the forms which are the most numerous in the Black Sea are either cosmopolite forms or such as are common in the northern seas, but not those which might have immigrated from the Mediterranean. In a notice published in the last volume of the *Memoirs of the Kieff Society of Naturalists*, M. Sovinsky points out, however, that the reverse opinion—which admits a close relationship of the Black Sea crustaceans with the Mediterranean ones—gains more and more ground during these last few years. The Mediterranean fauna was of course submitted to the influence of the northern faunas, and its northern forms might have found an appropriate medium in the less salt water of the Black Sea; but the Black Sea fauna looks rather as a part of the fauna of the Mediterranean basin, slowly modified by the medium it inhabits; this opinion is supported, in fact, by the kinship of several Black Sea forms with those of the Mediterranean and the Red Sea, and by the richness of the Black Sea fauna in mere varieties and in such forms as are purely local, the prevailing types of the fauna being still the cosmopolite ones. The Black Sea fauna would be thus but a part of the Mediterranean fauna, but much impoverished and modified to a great extent by the variety of local conditions.

RUSSIAN geologists do not seem to hesitate in admitting the aqueous origin of granitic rocks which formerly were unanimously considered as igneous and eruptive. The late Prof. Barbot de Marny adopted this theory during the last years of his life, and the same theory is supported now with regard to the Dneiper pegmatites, by M. Gouroff, in the *Memoirs of the Society of Naturalists* at the Kharkoff University (vol. xvi.). After a thorough study of the granitic rocks of the rapids of the Dnieper, he describes these rocks, consisting of orthoclase, plagioclase, quartz, and biotite (this last and the orthoclase being often substituted by chlorite and epidote) as granitites. These granitites always appear stratified, and alternate with granitic gneisses, their stratification being well developed with an inclination towards N. 70° E. at 60°. They are also crossed with numerous veins of pegmatite. The quartz of the pegmatite contains large microscopical inclusions of water, sometimes with carbonic acid, and with solutions of natrium and calcium chloride; it is coloured brown, which colour disappears when it is heated. The veins of pegmatite contain large crystals of quartz and orthoclase. They decrease towards their lower ends and terminate in accumulations of crystalline quartz. They very often interfere with veins of quartz, either crystalline (with microscopic inclusions of water), or opal-like. M. Gouroff proposes to discuss further the question as to the origin of the peg-

matite veins in another paper, but he meanwhile points out that these veins are subsequent to the formation of the granitite and gneiss, and that, like the quartz veins, they are of aqueous origin.

In connection with the celebration of the centenary of ballooning, some foolhardy aëronauts have been attempting to cross the Channel through the fickle air. One, named L'Hoste, who started on Friday night from Boulogne, was missing till yesterday, when news reached Paris from Antwerp that he had been rescued in the North Sea by a French lugger bound for that town.

The Swedish Academy of Agriculture has proposed to the Government that a sum of 50*l.* be granted to Dr. R. Lundberg for a visit to the International Fisheries Exhibition. The proposal will most likely be granted.

On May 28, between 6 and 7.30 p.m., a magnificent mirage was seen at Finsbo, in Norra Ryrs parish, Sweden. During nearly two hours, with intervals of three to four minutes, a panoramic landscape was seen, with mountains, lakes, forests, and farms. To the eye the view appeared as if only three-quarters to one (English) mile distant.

Last year several Swedish merchants contributed a sum of 100*l.* to enable the Swedish Doctor of Zoology, C. Bovallius, who has been travelling in Central America, to forward rare zoological specimens to the Upsala University. Herr Bovallius has from time to time sent some valuable collections of insects and birds to this institution.

The additions to the Zoological Society's Gardens during the past week include an Ourang-outang (*Simia satyrus* ♀) from Sumatra, presented by Mr. J. M. Vermont; two Duyker Boks (*Cephalophus mergens* ♂ ♀) from South Africa, presented by Mr. H. H. Trevor; a Philippine Paradoxure (*Paradoxurus prehensilis*) from the Philippine Islands, presented by Mr. A. Burgess; a King Parrakeet (*Aprosmictus scapulatus*) from Australia, presented by Mrs. Lewin; a Lesser Sulphur-crested Cockatoo (*Cacatua sulphurea*) from Moluccas, presented by J. Snowdon Henry, F.Z.S.; two Viperine Snakes (*Tropidonotus viperinus*), a Dark Green Snake (*Zamenis atrovirens*) from North Africa, presented by Mr. J. C. J. Church; two Aye-ayes (*Chiromys madagascariensis*) from Madagascar, a Carpet Snake (*Morelia variegata*) from Australia, received on approval; a Hybrid Luhdorf's Deer (between *Cervus leuhdorfi* ♂ and *C. canadensis* ♀), ten Australian Wild Ducks (*Anas superciliosa*), bred in the Gardens.

OUR ASTRONOMICAL COLUMN

Cometary Refraction.—M. W. Meyer, of the Observatory of Geneva, has published a discussion of three series of micrometrical observations, made during as many near approaches of the great comet of 1881 (1881 III.) to stars, when the latter were seen through the denser parts of the head of the comet, the immediate object of the micrometrical measures of distance between the nucleus and the star being the detection of any deflection or refraction of the light of the star in passing through the cometic nebulosity. This comet offered a great advantage in an investigation of the kind, inasmuch as its nucleus had perfectly the appearance of a fixed star. M. Gustave Cellérier had treated the question from a theoretical point of view in a memoir published in *Archives des Sciences Physiques et Naturelles*, of Geneva, of October 15, 1882; the conclusions are reproduced in abstract by M. Meyer, who has applied the resulting formulæ to the case in question. The first series of observations was made on June 29, 1881, when the comet passed close to the star 519 of *Durchmusterung* + 65°, which is No. 6594 in Oeltzen's Catalogue, of 7·8 mag. The second series, on July 13, when the comet approached the star ι Draconis (Hev.) within about 38″, and the third series on August 1, when it passed about 24″ from a star of 9·10 mag. For details of the method of treating the observations we must refer to M. Meyer's paper, which appears in *Mémoires de la Société de Physique et d'Histoire Naturelle de Genève*, t. xxviii.; he sums up his conclusions as follows:—"La substance dont la chevelure de la grande comète de 1881 a été composée s'est optiquement comportée comme un gaz, et sa puissance réfractive à une distance de 10,200 kil. du noyau a été pendant l'époque des observations de 0·0000093. La pression de ce gaz diminuait dans les régions étudiées proportionellement au carré de la distance au noyau." He does not venture to say, however, that this value exactly represents the refractive power of the comet, though he believes in a measurable force.

M. Meyer remarks that previous attempts to detect a deflection of light in traversing the substance of a comet had led only to negative results. Bessel availed himself of the conjunction of Halley's Comet with a star of the tenth magnitude on September 29, 1835, to discover by heliometric measures an effect of this kind, but without success. His measures have been subjected to a new reduction, in accordance with M. Cellérier's theory, by M. Meyer, though with similar negative result.

Kepler's Nova of 1604.—The position of this famous star is now favourably situated for observation. It is most readily found by reference to a star of 8·9 mag., which occurs in Argelander's southern zones, and which is No. 16872 of Oeltzen's Catalogue. The place of this star for 1883·0 is in right ascension 17h. 24m. 2·9s., declination – 21° 23′ 34″. By Prof. Schönfeld's reduction of the observations of Fabricius in 1604, Kepler's star would precede 25·3s. in R.A. 0′·8 to the north. There is a star 11·12m. preceding 17·9s. and 1′·6 south of Argelander's, and another 12m. preceding 33·2s. and 2′·7 north; it is to the latter object, which was observed by Prof. Winnecke in 1875, though not previously glimpsed with a refractor of 7 inches aperture, that attention may be chiefly directed. It is to be remarked that the position of Kepler's star is liable to greater uncertainty than that of Tycho's star in 1572. It is very desirable that whatever may be the result of examination of the vicinity, it should be put upon record (of course with the corresponding date) from time to time. The Chinese annals have references to more than one of their stellar class *Ke-sing* or "extraordinary stars," in earlier times, which must have been situate in the neighbourhood of Kepler's *Nova*.

The Binary Star, γ Coronæ Australis.—Several years since an orbit was calculated for this object by Prof. Schiaparelli, who made use of measures up to 1875, whence it appeared that the periastron passage would take place about the end of 1882. Mr. Downing, availing himself of measures to 1880, has applied small corrections to the elements found by the Milan astronomer, and fixes the periastron passage to 1883·203, the period of revolution being 54·985 years. The binary is therefore describing at present a critical portion of the orbit, and, it may be hoped, will not be neglected by those observers of double stars who can well command its position. The following are angles and distances calculated from the two orbits:—

	Downing Pos.	Dist.	Schiaparelli Pos.	Dist.
	°	″	°	″
1883·50	134·2	0·27	93·3	0·38
83·75	103·8	0·32	80·4	0·50
84·25	74·6	0·55	59·5	0·73

The Saturnian Satellite, Mimas.—M. Meyer, observing with the 10 inch refractor presented to the Observatory of Geneva by the late director, Prof. Plantamour, succeeded in obtaining, near the opposition of Saturn in 1881, several sets of measures of the faint satellite, *Mimas*, about the time of greatest elongation. Considering the small number of measures of this object which have been obtained even with the largest instruments, M. Meyer's success is worthy of attention. On two nights he secured complete series of measures, and on other occasions partial ones. We find, on adjusting the circular elements adopted in this column for prediction of the positions of *Mimas* (which were founded upon Washington observations and required but small correction) by Prof. Frisby's observation of the conjunction of the satellite with the minor axis of the ring southwards, on November 8, 1882, that M. Meyer's measures are closely represented.

GEOGRAPHICAL NOTES

AT the meeting of the Royal Geographical Society on Monday night Sir Henry Rawlinson read the following telegram, forwarded by the Eastern Telegraph Company from Zanzibar, with regard to the movements of Mr. Joseph Thomson:—"Thomson reached Dgare na Erobi, in Masai country, long. 37°, lat. 3·5, on May 5. Was compelled to flee during night to evade what could only have been a disastrous fight, through troubles raised by Fischer's caravan in front. Got safely back to Taveta, where he camped his men, and has come down to Mombasa with small party in seven marches to replenish his goods, which has become necessary in consequence of his retreat from Masai and prolonged detention at Taveta. Returns in a few days to Taveta to proceed by Arusha, probably in company of another caravan. Is in good health. Details by post."

THE Russian Geographical Society has awarded its great gold medal to H. W. Abich, Member of the Academy of Sciences, for his researches into the Geology of the Caucasus. The gold medal of Count Lütke has been awarded to W. K. Döllen, astronomer of the Pulkova Observatory, for his new improved instrument for the determination of latitudes and longitudes. Two other gold medals, for ethnographical and statistical works, have been awarded to M. Barsoff, for collections of songs of Northern Russia, and to M. Krasnoperoff for a statistical description of the Government of Perm. Small gold medals have been awarded to MM. Eklon and Roborovsk, who both accompanied M. Prshevalsky in his travels; to M. Oshanin, zoologist, for travels in Karategin, Darvaz, and Turkestan; and to M. Vitkovsky, for exploring graves of the Stone period about Irkutsk. Silver medals have been awarded to M. Lessar for levelling operations between Askabad and Seraks; to M. Schultz for the same between Orenburg and Lake Aral; to M. Brounoff, for researches on cyclones and anticyclones in Europe; to M. Gladysheff, for determinations of latitudes and longitudes in the Akhal-tekke oasis; to M. Kiseleff, for a journey to the Bi-han; to M. Rodionoff, for surveys in Karategin; to M. Slovtsoff, for a description of the district of Kokchetan; also four other medals for smaller ethnographical and statistical works.

M. LESSAR, who made so interesting a journey from Askabad to Mash had, continues to make a series of excursions in the same region. He went a second time to Mash-had *viâ* Khelat, and thence to Zurabad, Saraks, Merv, Charjui, and Khiva; then he made a barometric levelling from Askabad to Tejent, visited Merv a second time, and in December last journeyed in the mountain region of Khelat, Daraghez, and Attek, thus covering about 3300 miles from April to December.

THE proprietors of the *Melbourne Age* have despatched an exploring expedition to New Guinea.

WE mentioned in a preceding volume the late Barbot de Marny's theory as to the formation of the dunes (*barkhans*) in the steppe of Kyzyl-kum and the influence of the wind as a powerful agency in modifying the earth's surface in the steppes. We find now, in the *Zapiski* of the Kieff Society of Naturalists, several objections to this theory by M. Borschoff. Without denying the partial influence of the wind, he reduces it to a quite secondary agency, and decidedly opposes the wind-theory of the formation of *barkhans*. Wind may increase the *barkhans* to a certain amount, but their primary origin must be sought for elsewhere, and the *rôle* of the wind is far below what has been assumed. So hard a rock as the sandstone, permeated with iron and lime, of the Kara-kum and Kyzyl-kum steppes cannot be disintegrated by wind, unless it has been disintegrated beforehand by rains and rapid changes of temperature —both which conditions are missing in the steppes. Therefore on the Emba, the Ilik, the Irghiz, where the same sandstones occur—as devoid of vegetation as in the Kyzyl-kum, there are no such surfaces covered with *barkhans* as in the neighbourhood of Lake Aral. As a rule the dunes appear only where there are remains of former lakes, and in such cases they assume the directions of the shores of these former basins. Far from being dependent on the direction of the prevailing winds, the direction of the *barkhans* varies, even within short distances, and it follows the windings of the coast of Lake Aral. Thus, they inclose the Sary Cheganak bay, like the parallel steps of an amphitheatre, the same directions being also taken by the rocky ledges of the terraces of sandstone, even beneath the water of the bay. The close connection of these ridges with the former action of the interior sea is the more obvious, as these dunes—sometimes stratified in their interior—often contain remains of Aral mollusks, such as *Cardium rusticum*, *Dreissena polymorpha*, as also *Adacna vitrea*. Whole banks, from a quarter to half a foot thick, of these shells are found in the *barkhans*, and they are met with at distances of 27 miles from Lake Aral, and 70 feet above its level (at Sopak), or even 80 miles north of it, and 100 to 120 feet above its level (at the Toulagai hill), whilst the depressions between the *barkhans* contain deposits of salt, with the same shells, or with an alga similar to the Aralian *Zostera*. The primary origin of the *barkhans*, M. Borschoff says, can be discovered even now in the low coast ridges. These ridges once formed slowly increase afterwards by the accumulation of vegetation on their summits, and vegetation plays a most important part in their growth. Several Solaneæ, such as *Caroxylon*, or *Halostachys*, and Gramineæ, such as *Ærulops lævis*, grow on their summit, which is covered subsequently with various species of *Tamarix* and *Calligonum*. When deeply covered with vegetation, their further increase is due to the sand brought by the wind, the organic life still remaining a powerful agency of increase. But their original appearance must be sought for, it is contended, in the agency of water. M. Severtsoff's remarks on the influence of vegetation on the growth of the dunes, and those of the Turkestan railway expedition on the immobility of the dunes (already analysed in NATURE), go far to sustain M. Borschoff's conclusions.

AN expedition, under the direction of Col. Prshevalsky, is being organised for the purpose of scientific researches in Central Asia and Thibet. The expedition is expected to start in August next.

A SERIES of valuable papers on the island of Yezo now appearing in the *Japan Gazette* deserve the attention of geographers. They are from the pen of Capt. Blakiston, who received the gold medal of the Royal Geographical Society in 1861 for exploration on the Yang-tsze, and who has for many years resided at Hakodate, the principal port of Yezo. The papers, which have reached their fifteenth part, are so varied and complete that they may fairly be called an encyclopædia of the island. The geography, geology, fauna and flora, the progress made during the past twenty years by the Japanese administrators, the Ainos, the mineral productions are all treated, and in addition the records of numerous journeys over all parts of the island are given. It is to be hoped that these valuable papers will be published in a collected form, for no future account of Yezo will be complete in which copious reference is not made to them. The numerous reports of the *employés* of the Japanese Government to the Colonisation Department in Tokio, which are now so difficult to obtain, are largely quoted in notes

ACCORDING to a new survey of the rapids of the Dnieper, the total fall of the river, on a stretch of forty-six miles, from Ekaterinoslav to the Khortitsa Island at Alexandrovsk, is 106·5 feet. The aggregate fall of the nine rapids is 60·3 feet, and their aggregate length is 5335 yards, the greatest rapid being that of Nenasytetsky (the Insatiable) which has a fall of 19·5 feet and a length of 1867 yards. The discharge of water at the head of the rapids has been found, at a level 2·5 feet below the average, to be 27,934 cubic feet per second.

THE CAUSE OF EVIDENT MAGNETISM IN IRON, STEEL, AND OTHER MAGNETIC METALS[1]

THE extreme sensitiveness of the induction balance to all molecular changes in the structure of metals was remarked in my first paper on this subject to the Royal Society;[2] and in the case of iron and steel it is most remarkable, as the addition or subtraction of 1/500,000th part, or the addition of the smallest iron filing to an already large balanced mass of iron, is at once rendered evident and measurable.

Possessing such an invaluable instrument of research, I was desirous of investigating the molecular construction of iron and steel, but at once I met with a difficulty, viz. that magnetism itself completely changed the character of any piece of iron under investigation; consequently, finding no help or explanation of the effects produced from any accepted theories of magnetism, I was forced to investigate, by means of the induction balance, the

[1] Paper read before the Society of Telegraph Engineers and of Electricians, on May 24, 1883, by Prof. D. E. Hughes, F.R.S., Vice-President.
[2] "On an Induction Current Balance, and Experimental Researches made therewith."—*Proceedings Royal Society*, March 29, 1879, p. 56.

whole question of magnetism as existing in the interior of a magnet, and to determine the particular structure for each case, such as neutrality and polarity.

In a recent paper to the Royal Society, upon the theory of magnetism (*Proceedings Royal Society*, May 10, 1883), I described the use of and demonstrations obtained by the induction balance. In this paper I propose to confine myself to demonstrations that can be repeated without it, and whose effects can be observed by the aid of ordinary magnetic direction needles.

That magnetism is of a molecular nature has long been accepted, for it is evident that, no matter how much we divide a magnet, we still have its two poles in each separate portion, consequently we can easily imagine this division carried so far, that we should at last arrive at the molecule itself possessing its two distinctive poles, consequently all theories of magnetism attempt some explanation of the cause of this molecular polarity, and the reason for apparent neutrality in a mass of iron.

Coulomb and Poisson assume that each molecule is a sphere containing two distinct magnetic fluids, which in the state of neutrality are mixed together, but when polarised are separated from each other at opposite sides; and, in order to explain why these fluids are kept apart as in a permanent magnet, they had to assume, again, that each molecule contained a peculiar coercive force, whose functions were to prevent any change or mixing of these fluids when separated.

There is not one experimental evidence to prove the truth of this assumption; and as regards coercive force, we have direct experimental proof opposing this view, as we know that molecular rigidity or hardness, as in tempered steel, and molecular freedom of softness, as in soft iron, fulfil all the conditions of this assumed coercive force.

Ampère's theory, based upon the analogy of electric currents, supposes elementary currents flowing around each molecule, and that in the neutral state these molecules are arranged haphazard in all directions, but that magnetisation consists in arranging them symmetrically.

The objections to Ampère's theory are numerous. 1. We have no knowledge or experimental proof of any elementary electric currents continually flowing without any expenditure of energy. 2. If we admit the assumption of electric currents around each molecule, the molecule itself would then be electromagnetic, and the question still remains, What is polarity? Have the supposed electric currents separated the two assumed magnetic fluids contained in the molecule, as in Poisson's theory? or are the electric currents themselves magnetic, independent of the iron molecule?

In order to produce the supposed heterogeneous arrangement of neutrality, Ampère's currents would have either to change their position upon the molecule and have no fixed axis of rotation, or else the molecule, with its currents and polarities, would rotate, and thus be acting in accordance with the theory of De la Rive. 3. This theory does not explain why (as in the case of soft iron) polarity should disappear whenever the exciting cause is removed, as in the case of transient magnetisation. It would thus require a coercive force in iron to cause exactly one-half of the molecules to instantly reverse their direction in order to pass from apparent external polarity to that of neutrality.

The influence of mechanical vibrations and stress upon iron in facilitating or discharging its magnetism, as proved by Matteucci, 1847, in addition to the discovery by Page, 1837, of a molecular movement taking place in iron during its magnetisation, producing audible sounds, and the discovery by Dr. Joule, 1842, of the elongation of iron when magnetised, led De la Rive, in his remarkable "Treatise on Electricity," 1853, to give his theoretical views upon magnetism in the following remarkable words:—

"The whole of the magnetic molecular phenomena that we have been studying lead us to believe that the magnetisation of a body is due to a particular arrangement of its molecules, originally endowed with magnetic virtue, but which in the natural state are so arranged that the magnetism of the body that they constitute is not apparent. Magnetism would therefore consist in disturbing this state of equilibrium, or in giving to the particles an arrangement that makes manifest the property with which they are endowed, and not in developing it in them. The coercitive force should be the resistance of the molecules to change their relative positions."

Wiedemann, in 1861, gives a theory in which he admits the fluids of Poisson, or the elementary currents of Ampère, as the cause of polarity of the molecule, but believes that the molecules are turned in a general direction in the case of polarity, and that in neutrality, like Ampère's, the magnetic axes of the molecules are turned in all directions.

Maxwell, in his remarkable treatise on "Electricity and Magnetism," 1881, page 75, gives the following *résumé* of Weber's theory:—

"Weber's theory differs from Poisson's in assuming that the molecules of the iron are always magnets, even before the application of the magnetising force, but that in ordinary iron the magnetic axes of the molecules are turned indifferently in every direction, so that the iron, as a whole, exhibits no magnetic properties." And again, page 429, Maxwell says he agrees with Weber's views, and that neutrality, or unmagnetised iron, has the axes of its molecules placed indifferently in all directions, and that the act of magnetisation consists in turning all the molecules so that their axes are either rendered all parallel to one direction, or at least deflected in that direction.

I have quoted these several theories which admit of the inherent polarity of the molecule, and in that respect they entirely agree with my own; but the induction balance at once shows that they are erroneous in the most important part, for my researches have proved that neutrality is perfectly symmetrical, that there is no case of neutrality where the axes of the molecules are turned indifferently in all directions, and that we cannot obtain perfect neutrality except when the molecules form a complete closed circuit of attraction.

I believe that a true theory of magnetism should admit of complete demonstration, that it should present no anomalies, and that all the known effects should at once be explained by it.

From numerous researches I have gradually formed a theory of magnetism entirely based upon experimental results, and these have led me to the following conclusions:—

1. That each molecule of a piece of iron, steel, or other magnetic metal is a separate and independent magnet, having its two poles and distribution of magnetic polarity exactly the same as its total evident magnetism when noticed upon a steel bar-magnet.

2. That each molecule, or its polarity, can be rotated in either direction upon its axis by torsion, stress, or by physical forces such as magnetism and electricity.

3. That the inherent polarity or magnetism of each molecule is a constant quantity like gravity; that it can neither be augmented nor destroyed.

4. That when we have external neutrality, or no apparent magnetism, the molecules, or their polarities, arrange themselves so as to satisfy their mutual attraction by the shortest path, and thus form a complete closed circuit of attraction.

5. That when magnetism becomes evident, the molecules or their polarities have all rotated symmetrically in a given direction, producing a north pole if rotated in that direction as regards the piece of steel, or a south pole if rotated in the opposite direction. Also, that in evident magnetism we have still a symmetrical arrangement, but one whose circles of attraction are not completed except through an external armature joining both poles.

6. That we have permanent magnetism when the molecular rigidity, as in tempered steel, retains them in a given direction, and transient magnetism whenever the molecules rotate in comparative freedom, as in soft iron.

Experimental Evidences.—In the above theory the coercive force of Poisson is replaced by molecular rigidity and freedom; and as the effects of mechanical vibrations, torsion, and stress upon the apparent destruction and facilitation of magnetism is well known, I will, before demonstrating the more serious parts of the theory, cite a few experiments to prove that molecular rigidity fulfils all the requirements of an assumed coercive force.

The influence of vibrations, torsion, or stress of any kind upon a magnetised steel or iron rod may be seen by striking with a wooden mallet rods of hard and soft steel, also hard and soft iron previously magnetised to a known degree. The tempered steel, owing to its molecular rigidity, will lose but 5 per cent., the soft steel 60, hard iron 50, and soft Swedish iron 99 per cent. of its magnetism, the amount of loss depending not so much upon whether the metal be steel or iron, as upon its degree of hardness and softness; and as hard steel requires far more power to magnetise it to the same force than iron, it is possible to imagine a steel so hard that its molecules could not rotate, and that consequently no magnetism could be manifested from a given inducing cause, whilst a perfectly soft iron would give the maximum effect, and instantly return to its previous state. From this we might in error suppose that soft Swedish iron could not

retain its magnetism, and that its natural state would be zero, or neutrality. The apparent disappearance of magnetism, however, is here due to the extreme freedom of motion of its molecules allowing them at once to follow the comparatively feeble directing force of the earth's magnetism. We can demonstrate this by feebly magnetising a rod of soft iron held vertically, so that its north pole is at the lower portion. Upon removing the inducing magnet, or electromagnetic coil, we find that the rod retains a powerful north polarity; but if magnetised in a contrary sense, then we have only *traces* of magnetism left upon the withdrawal of the inducing cause. To succeed in this experiment, as in all others where soft iron is mentioned, we should use the best Swedish charcoal iron, thoroughly annealed at high temperature.

We find, again, that rods of steel or iron will lose far less magnetism when vibrated in the magnetic dip, or vertically, when their north poles are at the lowest extremity, than when horizontal, or still less than when their poles are contrary to those of the earth's field, and also that they will acquire their maximum magnetism from a given exciting cause when held vertically as described, and the molecules allowed greater freedom of motion to obey the directing influence by vibrations, torsion, stress, or blows upon the iron. Any influence that would tend to give greater freedom of motion, such as heat or mechanical trepidations, gives a far higher magnetic force to the iron than could be obtained without these aids.

In order to render visible the effects of motion upon magnetism, we may take two glass tubes, or ordinary phials, of any length or diameter, say, 10 centimetres in length by 2 centimetres in diameter. If we now put iron filings in these tubes, leaving about one-third vacant, so as to allow complete freedom in the filings when shaken, we find that each tube, when magnetised, retains an equal amount of residual magnetism, and that this all disappears upon slightly shaking the tube. We are thus imitating the effects of vibration. But if in one of these tubes we pour melted resin (in fact, any slightly viscous liquid, such as petroleum, suffices), we then render these filings more rigid, and then we can no longer produce by shaking the disappearance of its residual magnetism. In pouring in petroleum we have apparently been introducing a strong coercitive force, but we know that it can only have the mechanical effect of rendering the iron filings less free to turn, and so comparatively rigid. If we desire to see the effect of torsion, we have only to shake the filings so that when the tube is held horizontally the vacant space is above, and rotate it slightly (but without shaking) about a horizontal axis. Its remaining magnetism instantly disappears upon rotation, although we evidently have not changed the longitudinal position of its particles. A similar effect takes place upon a soft iron rod, for if we magnetise it and observe its remaining magnetism, we find that upon giving a slight torsion to this wire its remaining magnetism instantly disappears—a similar effect to that in the rotating tube of iron filings. But if the iron is rendered more rigid by hammering, or steel rendered hard and rigid by tempering, torsions or vibrations have but little effect, as in the case of the filings rendered rigid as above mentioned. Thus we have no longer need of an assumed mysterious coercive force to account for the retention of magnetism, for once knowing the mechanical qualities of iron and steel and their degree of molecular rigidity or hardness, we can at once predict their retentive magnetic powers.[1]

Rotation of Inherent Polarised Molecules.—Torsion, as well as mechanical vibrations, has, as we have seen, a powerful influence in aiding the molecules to overcome their inertia, and thus aid them to rotate in the direction of the inducing influence; and we may thus polarise strongly a flat, soft iron rod by simply bending or vibrating it when held vertically, and if we measure the magnetic force obtained we shall notice that the force is strictly relative to the degree of softness of the iron. Thus, with hard steel we should obtain only *traces* of polarisation, whilst with extremely pure, soft Swedish iron we obtain the maximum of force. The bar of iron or steel, being held in the earth's magnetic field, of infinite size compared with the bar, and infinitely homogeneous, cannot deflect or weaken its surrounding field. Its lower portion, being north, apparently strengthens it by its reaction, whilst its upper, south, apparently weakens the field; but, as Maxwell has shown, "the two poles of each molecule are equal and opposite, consequently the sum of each molecule and the whole mass must be zero."

[1] "On the Molecular Rigidity of Tempered Steel," by Prof. D. E. Hughes, F.R.S. (*Proceedings Institution of Mechanical Engineers*, pp 72-79, January, 1883.)

We have a far greater induced polarity in iron or steel when the iron is in thin bars or small wires, and this we should expect, as the external molecules rotate directly under the influence of the earth's magnetism, whilst those forming the interior of the bar either rotate feebly, or, as in the case of very thick bars, actually act as an armature, preventing by their influence free rotation of the exterior molecules.

Thus, as the sum of the two and equal polarities in a bar of iron is zero, it is evident that its polarity must be inherent. I have some remarkably pure soft Swedish iron wire, one millimetre in diameter, and as its inherent polar force seemed great when held vertically in the earth's magnetic field, I measured in the induction balance this force compared with a similar column of the magnetic atmosphere which it displaced. The inherent polarity of this wire, simply rendered evident by the earth's magnetism, was 15,600 times greater than the column it displaced.

We cannot, either by induction, conduction, or concentration, produce a greater force in another body of similar displacement or size, otherwise we could easily create power from a feeble source. Thus the enormously greater magnetic power observed in iron than the same column of air which it displaces must be due to the *inherent* polarity of its molecules.

Amongst numerous bars of iron upon which I have experimented, one of ordinary hoop-iron, 2 centimetres wide, 40 centimetres long, and $1\frac{1}{2}$ millimetre thick, not softened, possesses sufficient molecular rigidity to be apparently uninfluenced by the earth's magnetism. When this rod is rendered neutral we have but feeble polarity—mere traces when it is held vertically under the earth's magnetic influence; but if we apply a few successive torsions or vibrations to it when thus held, we have at once several thousand times greater polarity than before. Now, if iron had the power of deflecting or concentrating the earth's magnetism upon itself, it should not require the mechanical aid to molecular rotation given to it by these torsions or vibrations. Thus we are forced to conclude at least the existence of the inherent polarity of the molecules; and, if we admit this, we must also as a necessary consequence, admit the rotation of these molecules, else we cannot explain why mechanical vibrations allowing freedom of motion should always produce the polarity in accordance with the directing cause. I have already shown that torsion and vibrations *per se* are apparently destructive of magnetism; consequently in this case Poisson's two fluids and Ampère's parallel currents should, according to their theory, be mixed or heterogeneous, whilst, according to the views I am sustaining, the polarised molecules should obey, as compass needles, any magnetic directing cause whenever sufficient molecular freedom of motion allows free rotation.

The inherent polarity of iron may again be observed by drawing a flat rod of soft iron over one or both poles of a permanent magnet. This rod will then be powerfully magnetised, its remaining magnetism, when separated from the magnet, being sufficiently powerful to strongly deflect a suspended direction needle. A few slight torsions or vibrations will then completely discharge it. Now, suppose this operation repeated successively many thousand times, if there was no inherent polarity we should have gradually drawn all the polarity out of the magnet, and discharged it into the atmosphere. Nothing of the kind takes place. The molecules of the iron are simply rotated each time, and the only energy in work expended or lost comes from the arm of the experimenter, and the energy required would be strictly in accordance with the molecular freedom, or softness and hardness of the iron and steel; thus, whilst soft iron could be easily polarised and discharged by mechanical torsions, hard tempered steel would require a far greater amount.

Dr. Warren de la Rue, F.R.S., kindly aided me in this part of the research by passing a current from his well-known chloride of silver battery through iron and steel wires. A condenser of 42·8 microfarad capacity, charged by 3·360 cells, was used. We passed this enormous electric charge longitudinally through the wires, and observations were made as to whether any change whatever was produced in their quality or inherent polarity, the result being that these wires gave exactly the same magnetic polarity from a given directing or inducing cause as before, being similar in nature and degree, consequently this enormous electric force had not changed or destroyed the original inherent polarity.

If the molecules possess inherent polarity and rotate upon their axes, similar to a series of compass needles having a slight

degree of frictional rigidity, then, upon passing one pole of a magnet above them, they would turn symmetrically in one direction, and drawing the same pole of the magnet in the contrary direction would rotate them, and they would then remain symmetrically in the opposite direction.

A precisely similar effect takes place in a soft iron rod, placed east and west a few inches above a direction needle. Upon drawing the south pole of a powerful natural magnet at a few centimetres distance above the wire from east to west, the north polarities of the molecules successively turn in the direction of west, following the attraction of the south pole, as previously seen on the small compass needles. The rod is now magnetised with its north pole west, as indicated by the direction needle below any portion of this rod. Upon passing the same south pole of the natural magnet in a contrary direction, the molecules all rotate, their north poles still turning successively to the south pole of the permanent magnet until its arrival at the end from which the first magnetisation commenced. The rod has now entirely changed its polarity, and its north pole is east.

This phenomenon is well known in the ordinary magnetisation of rod , where care is taken to draw the magnet always in a similar direction, or the poles would be reversed at each to and fro drawing. To account for this on Coulomb-Poisson's theory it would be requisite that, first, all the fluids be separated with their north fluids symmetrically in one direction, but on drawing back the magnet these fluids would have to mix together, the north fluid passing through its south fluid to be finally opposite to its previous position, its coercive force doing the double work of allowing both fluids to mix and pass through each other, and finally keep them entirely apart. Ampère's theory would require that from a haphazard arrangement the molecules should become symmetrically arranged upon the first passage of the magnet, then upon its reversed direction one-half of the electric elementary currents should successively revolve in a contrary direction to arrive at neutrality before, finally, the other half followed the direction of the first half, and now all these currents would be revolving in the opposite direction to that upon the first magnetisation. We thus see that both these theories, whilst resting altogether upon assumption, are extremely complicated and improbable.

We might suppose, from the theory which I am advocating, that upon the rotation of the molecules there would be some disturbance or mechanical trepidation ; and such is found to be the case, as first observed by Page and afterwards verified by Dr. Joule and De la Rive, in the molecular sounds produced in iron upon its magnetisation. Reis's first telephone was founded upon these sounds, and Du Moncel has made numerous researches upon this subject.

In the last of my experiments cited the sounds are too feeble to be heard, but by the application of the microphone these trepidations at once become audible.

That molecules of iron and other metals rotate with time, whose period becomes shortened by mechanical vibrations, is well known in metallurgy, the ultimate result being generally the passage from a fibrous condition, as in iron wires, to a high degree of crystallisation. For many years I employed a circular vibrating spring as the regulator of speed of my printing telegraph instrument, and although this spring was so regulated by means of a frictional break, or "Frein," as not to surpass its limits of elasticity, these springs were constantly breaking after a few days' use, and as a matter of urgent necessity I made special researches into the cause of this breaking after a few days' constant vibratory action. I found at the point of rupture a high state of crystallisation. Fibrous iron would thus become thoroughly crystallised and break in one day ; the number of vibrations for an instrument in constant use during 24 hours being 1,209,600. Thus we could roughly estimate the life of iron in the form of one of these springs at 1,000,000 vibrations. Copper crystallised in one hour, and all metals and alloys were inferior to steel, except aluminium bronze. The latter springs would stand six weeks' constant use, or some 50,000,000 of vibrations. I finally resolved this problem by spreading the amount of vibrating work over a spiral spring containing 3 metres of steel rod wound into the same space as previously held by the straight rod of 30 centimetres ; by this means the average life of these springs has become five years. Evidently the molecules of these fibrous springs must have rotated under the vibrations, in order to produce crystals. The same phenomenon is observed in axles of carriages receiving constant trepidations, large crystals being always found at the point of fracture. Again, if we rapidly magnetise and demagnetise an iron rod, we have the production of evident heat, due to the constant motion of its molecules.

Maxwell describes an experiment of Beetz, in which an exceedingly small filament of iron was deposited by electrotype, under the influence of a strong magnetic field, in order to arrive at the inherent polarity of comparatively few molecules, and, as its magnetic force was very great, he regards the experiment as conclusive. My own experiments show that we have far less external magnetic force from a solid bar than from a thin tube or flat bar of the same surface exposed to a limited exciting cause. We know that magnetism does not penetrate to a very great depth, and we also know that, if to a thin steel permanent magnet we place another piece unmagnetised, or, better still, a rod of soft iron, its external polarity is greatly reduced, consequently the external evidence of polarity is not a direct measure of the degree of rotation, nor of the total inherent polarity of its mass. We may have a great superficial *external* rotation superposed upon rotations of an opposite nature, as will be seen later ; and thus the internal molecules of a magnet often act more or less as an external armature in closing its circle of attractions.

I have stated my belief that the molecule itself possesses its inherent polarity, which, like gravity, is an endowed quality for which we have no more reason to suspect the cause to be elementary electric currents than that elementary currents should be the cause of gravity, chemical affinity, or cohesion, and its polar power of crystallisation, most of which are affected by an electric current. We have a certain analogy between electric currents and magnetism, but not so great as the analogy between the magnetic polarity of a molecule and its other endowed qualities.

Magnetism, like chemical affinity, cohesion, and crystallisation, has its critical points. Faraday discovered that at red-yellow heat iron instantly lost its apparent polar magnetic power, to be as instantly restored at red heat, the critical point varying in iron, steel, &c., and being the lowest in nickel. This would be difficult to explain upon Ampère's theory, as we should have to admit the instant destruction or cessation of the elementary currents, to be again restored at a few degrees less temperature. It would be equally difficult to explain under my view, if it did not belong to a whole class of phenomena due to the possession by the molecules of various endowed qualities, of which chemistry and all our means of research can only teach us their critical points, without attempting to explain why, for instance, iron has a greater affinity for oxygen than gold. We know that it is so ; we know that the molecules of all matter are endowed with certain qualities having certain critical points, and I can see no reason for separating their magnetic inherent polarity from their numerous other qualities.

(*To be continued.*)

METERS FOR POWER AND ELECTRICITY[1]

THE subject of this evening's discourse, "Meters for Power and Electricity," is unfortunately, from a lecturer's point of view, one of extreme difficulty ; for it is impossible to fully describe any single instrument of the class without diving into technical and mathematical niceties which this audience might well consider more scientific than entertaining. If then in my endeavour to explain these instruments and the purposes which they are intended to fulfil in language as simple and as untechnical as possible, I am not as successful as you have a right to expect, I must ask you to lay some of the blame on my subject and not all on myself.

I shall at once explain what I mean by the term "meter," and I shall take the flow of water in a trough as an illustration of my meaning. If we hang in a trough a weighted board, then when the water flows past it the board will be pushed back ; when the current of water is strong the board will be pushed back a long way ; when the current is less it will not be pushed so far ; when the water runs the other way the board will be pushed the other way. So by observing the position of the board we can tell how strong the current of water is at any time. Now suppose we wish to know, not how strong the current of water is at this time or at that, but how much water altogether has passed through the trough *during* any time, as for instance one hour. Then if we have no better instrument than the weighted board, it will be necessary to observe its

[1] Lecture at the Royal Institution, by Mr. C. Vernon Boys, March 2.

position continuously, to keep an exact record of the corresponding rates at which the water is passing, every minute, or, better, every second, and to add up all the values obtained This would of course be a very troublesome process. There is another kind of instrument which may be used to measure the flow of the water: a paddle-wheel or screw. When the water is flowing rapidly the wheel will turn rapidly; when slowly, the wheel will turn slowly; and when the water flows the other way the wheel will turn the other way, so that if we observe how fast the wheel is turning we can tell how fast the water is flowing. If now we wish to know how much water altogether has passed through the trough, the number of turns of the wheel, which may be shown by a counter, will at once tell us. There are therefore in the case of water two kinds of instruments, one which measures *at* a time, and the other *during* a time. The term meter should be confined to instruments of the second class only.

As with water so with electricity, there are two kinds of measuring instruments, one, of which the galvanometer may be taken as a type, which shows by the position of a magnet how strong a current of electricity is *at* a time, and the other, which shows how much electricity has passed *during* any time. Of the first, which are well understood, I shall say nothing; the second, the new electric meters and the corresponding meters for power, are what I have to speak of to-night.

It is hardly necessary for me to mention the object of making electric meters. Every one who has had to pay his gas bill once a quarter probably quite appreciates what the electric meters are going to do, and why they are at the present time attracting so much attention. So soon as you have electricity laid on in your houses, as gas and water are laid on now, so soon will a meter of some sort be necessary in order that the companies which supply the electricity may be able to make out their quarterly bills, and refer complaining customers to the faithful indications of their extravagance in the mysterious cupboard in which the meter is placed.

The urgent necessity for a good meter has called such a host of inventors into the field that a complete account of their labours is more than any one could hope to give in an hour. Since I am one of this host I hardly like to pick out those inventions which I consider of value. I cannot describe all, I cannot act as a judge and say these only are worthy of your attention, and I do not think I should be acting fairly if I were to describe my own instruments only and ignore those of every one else. The only way I see out of the difficulty is to speak more particularly about my own work in this direction, and to speak generally on the work of others.

I must now ask you to give your attention for a few minutes to a little abstract geometry. We may represent any changing quantity, as for instance the strength of an electrical current, by a crooked line. For this purpose we must draw a straight line to represent time, and make the distance of each point of the crooked line above the straight line a measure of the strength of the current at the corresponding time. The size of the figure will then measure the quantity of electricity that has passed, for the stronger the current is the taller the figure will be, and the longer it lasts the longer the figure will be, either cause makes both the quantity of electricity and the size of the figure greater and in the same proportion; so the one is a measure of the other. Now it is not an easy thing to measure the size of a figure: the distance round it tells nothing; there is, however, a geometrical method by which its size may be found Draw another line, with a great steepness where the figure is tall, and with a less steepness where the height is less, and with no steepness or horizontal where the figure has no height. If this is done accurately, the height to which the new line reaches will measure the size of the figure first drawn; for the taller the figure is, the steeper the hill will be; the longer the figure, the longer the hill; either cause makes both the size of the figure and the height of the hill greater, and in the same proportion; so the one is a measure of the other; and so, moreover, is the height of the hill, which can be measured by a scale, a measure of the quantity of electricity that has passed.

The first instrument that I made, which I have called a "cart" integrator, is a machine which, if the lower figure is traced out, will describe the upper. I will trace a circle; the instrument follows the curious bracket-shaped line that I have already made sufficiently black to be seen at a distance, the height of the new line measures the size of the circle, the instrument has squared the circle. This machine is a thing of mainly theoretical interest, my only object in showing it is to explain the means by which I have developed a practical and automatic instrument of which I shall speak presently. The guiding principle in the cart integrator is a little three-wheeled cart, whose front wheel is controlled by the machine. This, of course, is invisible at a distance, and therefore I have here a large front wheel alone. On moving this along the table, any twisting of its direction instantly causes it to deviate from its straight path; now suppose I do not let it deviate, but compel it to go straight, then at once a great strain is put upon the table which is urged the other way. If the table can move it will instantly do so. A table on rollers is inconvenient as an instrument, let us therefore roll it round into a roller, then on moving the wheel along it the roller will turn, and the amount by which it turns will correspond to the height of the second figure drawn by the cart integrator. If, therefore, the wheel is inclined by a magnet under the influence

FIG. 1.

of an electric current, or by any other cause, the whole amount of which we wish to know, then the number of turns of the roller will tell us this amount; or to go back to our water analogy, if we had the weighted board to show current strength, and had not the paddle-wheel to show total quantity, we might use the board to incline a disk in contact with a roller, and then drag the roller steadily along by clockwork. The number of turns of the roller would give the quantity of water. Instruments that will thus add up continuously indications at a time, and so find amounts during a time, are called integrators.

The most important application that I have made at present of the integrator described is what I have called an engine-power meter. The instrument is on the table, but as it is far too small to be seen at a distance, I have arranged a large model to illustrate its action. The object of this machine is to measure how much work an engine has done during any time, and show

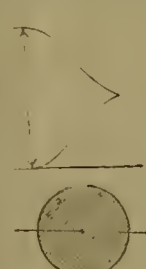

FIG. 2.

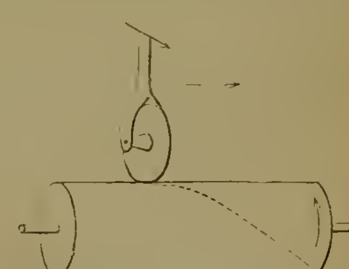

FIG. 3.

the result on a dial, so that a workman may read it off at once without having to make any calculations.

Before I can explain how work is measured, perhaps I had better say a few words about the meaning of the word "work." Work is done when pressure overcomes resistance, producing motion. Neither motion nor pressure alone is work. The two factors, pressure and motion, must occur together. The work done is found by multiplying the pressure by the distance moved. In an engine, steam pushes the piston first one way, then the other, overcomes resistance, and does work. To find this, we must multiply the pressure by the motion at every instant, and add all the products together. This is what the engine-power meter does, and it shows the continuously growing result on a dial. When the piston moves it drags the cylinder along, where the steam presses the wheel is inclined. Neither action alone causes the cylinder to turn, but when they occur together the cylinder turns, and the number of turns registered on a dial shows with mathematical accuracy how much work has been done.

In the steam-engine work is done in an alternating manner,

and it so happens that this alternating action exactly suits the integrator. Suppose, however, that the action whatever it may be, which we wish to estimate is of a continuous kind, such for instance as the continuous passage of an electric current. Then, if by means of any device, we can suitably incline the wheel, so long as we keep pushing the cylinder along, so long will its rotation measure and indicate the result; but there must come a time when the end of the cylinder is reached. If then we drag it back again, instead of going on adding up, it will begin to take off from the result, and the hands on the dial will go backwards, which is clearly wrong. So long as the current continues, so long must the hands on the dial turn in one direction. This effect is obtained in the instrument now on the table, the electric energy meter, in this way. Clockwork causes the cylinder to travel backwards and forwards by means of what is called a

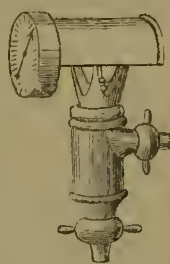

Fig. 4.

mangle motion, but instead of moving always in contact with one wheel, the cylinder goes forward in contact with one, and back in contact with another on its opposite side. In this instrument the inclination of the wheels is effected by an arrangement of coils of wire, the main current passing through two fixed concentric solenoids, and a shunt current through a great length of fine wire on a movable solenoid, hanging in the space between the others. The movable portion has an equal number of turns in opposite directions, and is therefore unaffected by magnets held near it. The effect of this arrangement is that the energy of the current, that is, the quantity multiplied by the force driving it, or the electrical equivalent of mechanical power, is measured by the slope of the wheels, and the amount of work done by the current during any time, by the number of turns of the cylinder, which are registered on a dial. Professors Ayrton and

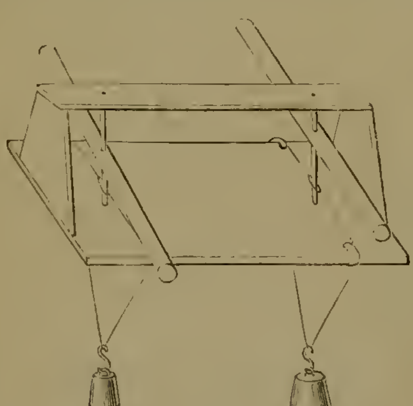

Fig. 5.

Perry have devised an instrument which is intended to show the same thing. They make use of a clock, and cause it to go too fast or too slow by the action of the main on the shunt current; the amount of wrongness of the clock, and not the time shown, is said to measure the work done by the current. This method of measuring the electricity by the work it has done is one which has been proposed to enable the electrical companies to make out their bills.

The other method is to measure the amount of electricity that has passed without regard to the work done. There are three lines on which inventors have worked for this purpose. The first, which has been used in every laboratory ever since electricity has been understood, is the chemical method. When electricity passes through a salt solution, it carries metal with it, and deposits it on the plate by which the electricity leaves the liquid. The amount of metal deposited is a measure of the quantity of electricity. Mr. Sprague and Mr. Edison have adopted this method; but as it is impossible to allow the whole of a strong current to pass through a liquid, the current is divided; a small proportion only is allowed to pass through. Provided that the proportion does not vary, and that the metal never has any motions on its own account, the increase in the weight of one of the metal plates measures the quantity of electricity.

The next method depends on the use of some sort of integrating machine, and this being the most obvious method, has been attempted by a large number of inventors. Any machine of this kind is sure to go, and is sure to indicate something, which will be more nearly a measure of the electricity, as the skill of the inventor is greater.

Meters for electricity of the third class are dynamical in their action, and I believe that what I have called the vibrating meter was the first of its class. It is well known that a current passing round iron makes it magnetic. The force which such a magnet exerts is greater when the current is greater, but it is not simply proportional; if the current is twice or three times as strong, the force is four times or nine times as great, or generally the force is proportional to the square of the current. Again, when a body vibrates under the influence of a controlling force, as a pendulum under the influence of gravity, four times as much force is necessary to make it vibrate twice as fast, and nine times to make it vibrate three times as fast; or generally the square of the number measures the force. I will illustrate this by a model. Here are two sticks nicely balanced on points, and drawn into a middle position by pieces of tape to which weights may be hung. They are identical in every respect. I will now hang a 1 lb. weight to each tape, and let the pieces of wood swing. They

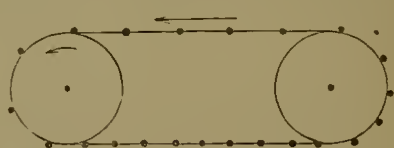

Fig. 6.

keep time together absolutely. I will now put 2 lbs. on one tape. It is clear that the corresponding stick is going faster, but certainly not twice as fast. I will now hang on 4 lbs. One stick is going at exactly twice the pace of the other. To make one go three times as fast, it is obviously useless to put on 3 lbs., for it takes 4 to make it go twice as fast. I will hang on 9 lbs. One now goes exactly three times as fast as the other. I will now put 4 lbs. on the first, and leave the 9 lbs. on the second; the first goes twice while the second goes three times. If instead of a weight we use electromagnetic force to control the vibrations of a body, then twice the current produces four times the force, four times the force produces twice the rate; three times the current produces nine times the force, nine times the force produces three times the rate, and so on; or the rate is directly proportional to the current strength. There is on the table a working meter made on this principle. I allow the current that passes through to pass also through a galvanometer of special construction, so that you can tell by the position of a spot of light on a scale the strength of the current. At the present time there is no current; the light is on the zero of the scale, the meter is at rest. I now allow a current to pass from a battery of the new Faure-Sellon-Volckmar cells which the Storage Company have kindly lent me for this occasion. The light moves through one division on the scale, and the meter has started. I will ask you to observe its rate of vibration. I will now double the current; this is indicated by the light moving to the end of the second division on the scale: the meter vibrates twice as fast. Now the current is three times as strong, now four times, and so on. You will observe that the position of the spot of light and the rate of vibration always correspond. Every vibration of the meter corresponds to a definite quantity of electricity, and causes a hand on a dial to move on one step. By looking at the dial, we can see how many vibrations there have been, and therefore how much electricity has passed. Just as the vibrating sticks in the model in time come to rest, so the vibrating part of the meter would in time do the same, if it were not kept going by an impulse automatically given to it

when required. Also, just as the vibrating sticks can be timed to one another by sliding weights along them, so the vibrating electric meters can be regulated to one another, so that all shall indicate the same value for the same current, by changing the position or weight of the bobs attached to the vibrating arm.

The other meter of this class, Dr. Hopkinson's, depends on the fact that centrifugal force is proportional to the square of the angular velocity. He therefore allows a little motor to drive a shaft faster and faster, until centrifugal force overcomes electromagnetic attraction, when the action of the motor ceases. The number of turns of the motor is a measure of the quantity of electricity that has passed.

I will now pass on to the measurement of power transmitted by belting. The transmission of power by a strap is familiar to every one in a treadle sewing-machine or an ordinary lathe. The driving force depends on the difference in the tightness of the two sides of the belt, and the power transmitted is equal to this difference multiplied by the speed; a power-meter must, therefore, solve this problem—it must subtract the tightness of one side from the tightness of the other side, multiply the difference by the speed at every instant, and add all the products together, continuously representing the growing amount on a dial. I shall now show for the first time an instrument that I have devised, that will do all this in the simplest possible manner. I have here two wheels connected by a driving band of indiarubber, round which I have tied every few inches a piece of white silk ribbon. I shall turn one a little way, and hold the other. The driving force is indicated by a difference of stretching, the pieces of silk are much further apart on the tight side than they are on the loose. I shall now turn the handle and cause the wheels to revolve; the motion of the band is visible to all. The indiarubber is travelling faster on the tight side than on the loose side, nearly twice as fast; this must be so, for as there is less material on the tight side than on the loose, there would be a gradual accumulation of the indiarubber round the driven pulley, if they travelled at the same speed; since there is no accumulation, the tight side must travel the fastest. Now it may be shown mathematically that the difference in the speeds is proportional both to the actual speed and to the driving strain; it is therefore a measure of the power or work being transmitted, and the difference in the distance travelled is a measure of the work done. I have here a working machine which shows directly on a dial the amount of work done; this I will show in action directly. Instead of indiarubber, elastic steel is used. Since the driving-pulley has the velocity of the tight side, and the driven of the loose side of the belt, the difference in the number of their turns, if they are of equal size, will measure the work. This difference I measure by differential gearing which actuates a hand on a dial. I may turn the handle as fast as I please; the index does not move, for no work is being done. I may hold the wheel and produce a great driving strain; again the index remains at rest, for no work is being done. I now turn the handle quickly, and lightly touch the driven wheel with my finger. The resistance, small though it is, has to be overcome; a minute amount of work is being done, the index creeps round gently. I will now put more pressure on my finger, more work is being done, the index is moving faster; whether I increase the speed or the resistance the index turns faster; its rate of motion measures the power, and the distance it has moved, or the number of turns, measures the work done. That this is so I will show by an experiment. I will wind up in front of a scale a 7 lb. weight; the band has turned one-third round. I will now wind a 28 lb. weight up the same height; the hand has turned four-thirds of a turn. There are other points of a practical nature with regard to this invention which I cannot now describe.

There is one other class of instruments which I have developed of which time will let me say very little. The object of this class of instruments is to divide the speed with which two registrations are being effected, and continuously record the quotient. In the instrument on the table two iron cones are caused to rotate in time with the registration; a magnetised steel reel hangs on below. This reel turns about, and runs up or down the cones until it finds a place at which it can roll at ease. Its position at once indicates the ratio of the speeds which will be efficiency, horse-power per hour, or one thing in terms of another. Just as the integrators are derived from the steering of an ordinary bicycle, so this instrument is derived from the double steering of the "Otto" bicycle.

Though I am afraid that I have not succeeded in the short time at my disposal in making clear all the points on which I have touched, yet I hope that I have done something to remove the very prevalent opinion that meters for power and electricity do not exist.

THE PERMIAN SYSTEM IN RUSSIA [1]

A QUESTION which has during the last few years occupied Russian geologists is whether the upper horizon of the "mottled marls," which were considered by Murchison as Permian, must be still regarded as such, or rather as a member of the Trias—an opinion strongly advocated by several eminent geologists in Russia. The question is a large one, the mottled marls being the most widely-spread member of Murchison's Permian formation in Russia, and covering it almost on the whole of the surface it occupies in Russia in Europe. Were the Triassic origin of the mottled marls an established fact, the whole aspect of a geological map of Russia would be changed, and so it was on the map published in 1870 by a late member of the Academy, M. Helmersen, and on the map of the western slope of the Ural Mountains by Prof. Meller. The question is thus the subject of much controversy, and a whole series of papers is devoted to it in the *Memoirs of the Kazan Society of Naturalists* and elsewhere. The last of this series is a paper by Prof. Stuckenberg, which states the present aspect of the question and enables us to summarise the controversy in its broad features.

Murchison's Permian system covers, as is known, no less than 6600 square miles in eastern Russia, from the province of Archangel in the north to that of Ufa in the south, and from Nijni-Novgorod in the west to Perm and Orenburg in the east; isolated islands of it appear on the surface in the provinces of Astrakhan, Kharkov, and Ekaterinoslav. The evidence itself of the basin where the Permian formation was deposited necessarily implies a great variety of lithological characters, and in fact it includes, besides the dolomitic limestones, a very great variety of marls, clays, sandstones, and conglomerates, the limestones occupying separate basins in the middle parts, whilst the marls, clays, sandstones, and conglomerates have the appearance of coast deposits of the Permian Sea.

In the central parts of the basin (Kazan, Samara), the dolomitic limestones are covered with a thick sheet of mottled marls, with sandstones, conglomerates, clays, and isolated thinner sheets of a tuff-like limestone. This series covers, however, not only the dolomitic limestone but also, as has been said, nearly the whole of the Permian deposits of European Russia, confounding itself with the Permian marls and sandstones, as is, for instance, the case—M. Stuckenberg says—in the provinces of Vyatka, Nijni-Novgorod, Kazan, and Samara. Palæontological evidence, however, is scarce as to the upper mottled marls, so that Murchison himself made the suggestion that they may belong perhaps to a more recent formation; he even proposed to give them on his map a lighter colour than the remainder of the Permian formation.

The mottled marls were considered as Permian until 1855, when Prof. Wagner published a geological map in which he classified them as Triassic. Later on, Marcou, in 1858, and Ludwig, in his "Dias and Trias," in 1859, arrived, independently of Prof. Wagner, at the same conclusion. In 1864 Prof. Barbot de Marny discovered in a sandstone belonging to this group a fragment of an *Equisetites columnaris*, Sternb. (*Calamites arenaceus*, Brongn.), and this discovery, confirming former stratigraphical and lithological considerations, induced the majority of Russian geologists to consider since the mottled marls as a part of the Trias. This view was adopted, as said, by Helmersen and by Prof. Meller. But still, as the mottled marls are very poor in organic remains, and the whole question beset with difficulties, the controversy continued. Murchison found in these marls small *Cytherinæ* and shells like *Cyclas*, together with some remains of fishes and casts of *Mytilus*. Prof. Golovkinsky discovered microscopic remains of crustaceans and some fragments of shells, whilst the late M. Eichwald found remains of *Estheria exigua* and *Beyrichia Pyrrhæ*, in a deposit which M. Stuckenberg considers as belonging to the same group. As to the find by Prof. Wagner of the *Voltzia heterophylla* at Abdi, close by Mamadysh, together with remains of the fishes *Amblypterus Alberti* and *Saurichthys Mougeoti*, M. Stuckenberg

[1] "The Upper Mottled Marls and their Relations to other Members of the Permian System," by A. Stuckenberg. (*Memoirs of the Kazan Societ of Naturalists*, vol. xi. fasc. 2; Kazan, 1882.

doubts, first, the accuracy of the determination, and adds that the *Voltzia* was not found in the mottled marls, but in deposits "parallel to the Permian limestone."

The Zechstein (dolomites, dolomitic limestones, oolite, and gypsum), which reaches a great thickness in the provinces of Kazan and Samara, is a formation which was contemporary with the Permian marls, sandstones, and conglomerates which are widely spread in the provinces of Kazan, Nijni, Vyatka, Perm, Ufa, and Orenburg. On the places where both meet together, the Zechstein penetrates in the shape of thinner sheets into the marls. The copper sandstones of the Ural also would be, according to the same author, contemporary with the Zechstein. These marls and sandstones have a characteristic fauna, and MM. Stuckenberg and Zaïtseff discovered in them the following fossils:—*Lingula orientalis*, Golovk.; *Unio umbonatus*, Fisch.; *Unio castor*, Eichw.; *Aucella Hausmanni*, Goldf.; *Estheria exigua*, Eichw.; *Beyrichia Pyrrhæ*, Eichw.; and remains of ganoid fishes and lizards. These fossils are characteristic of the group, but it contains also the Zechstein fossils, *Stenopora columnaris*, Schl., *Schizodus obscurus*, Gein., *Schizodus rossicus*, Vern., *Nucula Beyrichi*, Bron., *Murchisonia subangulata*, Vern., *Gervillia sulcata*, Gein., *Gervillia seratophaga*, Schl., *Hinnites* (*Avicula*) *speluncaria*, Schloth., *Arca Kingiana*, Vern., *Clidophorus Pallasi*, Vern., *Terebratula elongata*, Schl., *Productus Cancrini*, Vern., *Camarophoria Schlotheimi*, Buch., and *Spirifer rugulatus*, Kut. The flora of this series is characterised by many Coniferæ (among others, the *Uhlmannia Bronnii* and *brevifolia*) Noeggerathiæ (*expansa* and *cuneifolia*), ferns, &c. These deposits are thus Permian, and it is worthy of notice that they contain the *Unio umbonatus* and *castor*, the *Estheria exigua*, and the *Beyrichia Pyrrhæ*.

As to the upper mottled marls, which are precisely the subject of the controversy, there was discovered in them but a very few fossils, by MM. Krotoff and Stuckenberg, namely, the four just mentioned (*Unio umbonatus*, *Unio castor*, *Estheria exigua*, and *Beyrichia Pyrrhæ*), on the Volga at Tetushi, and the same in the Government of Vyatka, where the marls contain sheets of limestone; besides, M. Krotoff found Zechstein fossils, as *Arca Kingiana*, in the tuff-like limestone on the Volga, which M. Stuckenberg considers as belonging to the same series. Finally, there was discovered during a boring at Mount Bogdo (Astrakhan), in sandstones and conglomerates, a series of Permian fossils (*Matica minima*, Brown, *Turbonila volgensis*, Golowk,, *Gervillia antiqua*, Mün., *Clidophorus Hollebeni*, *Clidophorus Pallasi*, Vern., *Schizodus rossicus*, Vern., *S. obscurus*, Gein., *Nucula Beyrichi*, Brown, *Leda speluncaria*, Gein., and *Hinnites* (*Avicula*) *speluncaria*, Schloth. M. Stuckenburg, considering the Bogdo sandstones as contemporary with the upper mottled marls, gives to it great weight; but it must be observed that the contemporaneity of the Bogdo marls with the upper mottled marls of the Volga is all but established.

As to the palæontological evidence produced for considering the upper mottled marls as Triassic, namely, those found of the Triassic, *Equisetites columnaris* (*Calamites arenaceus*), *Voltzia heterophylla*, and *Estheria minuta*, M. Stuckenburg considers it unsatisfactory, and points out that the *Voltzia heterophylla* was found rather in Permian deposits; and that Mr. Jones, in his "Monograph of the Fossil Estheriæ," considers the *Estheria minuta* of the Russian mottled marls as different from the *E. minuta*, Brongn., and rather like to the *E. tenella* of Jordan, which last belongs to the Permian and Carboniferous of Western Europe. As to the *Calamites arenaceus*, found by Barbot de Marny, F. Römer, in the last edition of his "Lethea geognostica," remarks that it is too badly preserved to be a decisive evidence. He concludes, therefore, that contrary to the opinion of almost all Russian geologists, that the mottled marls ought to be considered again as Permian. But, as seen from the above summary, it will be much more prudent to conclude that the whole question still remains open for further investigation.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE

CAMBRIDGE.—The Rede Lecture was delivered on Tuesday in the Senate House by Prof. Huxley, the subject being "The Origin of the Existing Forms of Animal Life, Construction or Evolution?" There were at least eleven hundred persons present, and amongst them nearly all the University dignitaries now in residence.

In the second part of the Natural Sciences Tripos sixteen men and one lady are placed in the first class; of this Mr. Harmer of King's College is distinguished in Zoology and Comparative Anatomy; Mr. Reid of Cavendish College in Human Anatomy; and Mr. Sharrington of Caius College in Physiology.

Prof. Hughes has been elected to a Professorial Fellowship at Clare College.

Messrs. P. Frost, I. Todhunter, and Joseph Wolstenholme are to receive the degree of Doctor in Science.

The Woodwardian Professor dissents strongly from the proposal to place the Sedgwick Museum on the Downing Street site in front of the new museums.

SCIENTIFIC SERIALS

THE *Journal of Anatomy and Physiology* for April, 1883, contains:—A contribution to the study of Spina bifida, encephalocele, and anencephalus, by Prof. Cleland (Plates 11 and 12).—On the minute structure of the palatine nerves of the frog, and the termination of nerves in blood-vessels and glands, by Prof. W. Stirling and J. F. Macdonald (Plate 13).—On the lymphatics of Periosteum, by Drs. George and F. Elizabeth Hoggan (Plate 14).—The brachial plexus of the macaque monkey, and its analogy with that of man, by W. T. Brooks.—A case of primary sarcoma of the pleura, by R. W. Greenish (Plate 15).—Infiltrating carcinoma of the breast, by Dr. G. Barling.—Observations of the diameters of human vertebræ in different regions, by Dr. R. J. Anderson.—On a simple form of Lippman's capillary electrometer useful to physiologists, by Prof. McKendrick.—On so-called sponge-grafting, by Drs. K. Franks and P. S. Abraham (Plate 16).—The valvular action of the larynx, by Drs. T. L. Brunton and T. Cash.—Origin of the internal circumflex from the deep epigastric artery, by Dr. A. Thomson.—On cervical ribs and the so-called bicipital ribs in man in relation to the corresponding structures in the Cetacea, by Prof. Turner.—On a new form of ether microtome, by Dr. Cathcart.—On right-sided sigmoid flexure and rectum, by Dr. E. E. Maddox.—A note to Mr. Haswell's paper on myology of pigeon.

THE *Quarterly Journal of Microscopical Science* for April, 1883, contains:—On the anatomy and development of *Peripatus capensis*, by the late Prof. F. M. Balfour, edited by Professors Moseley and Sedgwick (Plates 13 to 20).—On a morphological variety of *Bacillus anthracis*, by Dr. E. Klein, with notes thereon by Prof. Ray Lankester (Plate 21).—Note on a pink Torula, by H. Marshall Ward (Plate 22).—On double staining nucleated blood corpuscles with anilin dyes, by Dr. V. Harris.—Some recent researches on the continuity of the protoplasm through the walls of vegetable cells, by W. Gardiner.—Review of recent researches on Spermatogenesis, by J. E. Bloomfield.—Note on a minute point in the structure of the spermatozoon of the newt, by G. F. Dowdeswell.—On the existence of Spengel's olfactory organ and of paired genital ducts in the pearly nautilus, by Prof. Ray Lankester and A. G. Bourne.

SOCIETIES AND ACADEMIES

LONDON

Royal Society, April 12.—"On a New Crinoid from the Southern Sea." By P. Herbert Carpenter, M.A., Assistant Master at Eton College. Communicated by W. B. Carpenter, C.B., M.D., F.R.S.

Among the collections of the late Sir Wyville Thomson, a small *Comatula* has recently been discovered which was dredged by the *Challenger* at a depth of 1800 fathoms in the Southern Sea. Although it is unusually small, the diameter of the calyx being only 2 mm., the characters presented by this form are such as to render it by far the most remarkable among all the types of recent Crinoids, whether stalked or free. The name proposed for it is *Thaumatocrinus renovatus*.

But it is distinguished by four striking peculiarities:—

(1.) The presence of a closed ring of basals upon the exterior of the calyx.

(2.) The persistence of the oral plates of the larva, as in *Hyocrinus* and *Rhizocrinus*.

(3.) The separation of the primary radials by interradials which rest on the basals.

(4.) The presence of an arm-like appendage on the interradial plate of the anal side.

Taking these in order—

(1.) No adult *Comatula*, except the recent *Atelecrinus* and

some little-known fossils, has a closed ring of basals; and even in *Atelecrinus* they are quite small and insignificant.

(2.) In all recent *Comatulæ*, in the *Pentacrinidæ*, and in *Bathycrinus*, the oral plates of the larva become resorbed as maturity is approached. In *Thaumatocrinus*, however, they are retained, as in *Hyocrinus*, *Rhizocrinus*, and *Holopus*, representatives of three different families of Neocrinoids.

(3.) There is no Neocrinoid, either stalked or free, in which the primary radials remain permanently separated as they are in *Thaumatocrinus*, and for a short time after their first appearance in the larva of ordinary Crinoids. The only Palæocrinoids presenting this feature are certain of the *Rhodocrinidæ*, *e.g.* *Reteocrinus*, *Rhodocrinus*, *Thylacocrinus*, &c. In the two latter and in the other genera which have been grouped together with them into the section *Rhodocrinites* there is a single interradial intervening between every two radials, and resting on a basal just as in *Thaumatocrinus*. But in the Lower Silurian *Reteocrinus* the interradial areas contain a large number of minute pieces of irregular form and arrangement.

(4.) It is only, however, in *Reteocrinus* and in the allied genus *Xenocrinus*, Miller, which is also of Lower Silurian age, that an anal appendage similar to that of *Thaumatocrinus* is to be met with.

Of the four distinguishing characters of *Thaumatocrinus*, therefore, one appears in one or perhaps in two genera of *Comatulæ*; another is not to be met with in any *Comatula*, though occurring in certain stalked Crinoids; while the two remaining characters are limited to one family of the Palæocrinoids, one of them being peculiar to one or at most two genera which are confined to the Lower Silurian rocks.

Their reappearance in such a specialised type as a recent *Comatula* is therefore all the more striking.

Geological Society, May 23.—J. W. Hulke, F.R.S., president, in the chair.—Ernest Le Neve Foster and Richard Bullen Newton were elected Fellows of the Society.—The following communications were read:—On the basalt glass (tachylyte) of the Western Isles of Scotland, by Prof. J. W. Judd, F.R.S., Sec.G.S., and G. A. J. Cole, F.G.S. Basalt glass or tachylyte is a rare rock, although very widely distributed. In the Western Isles of Scotland it has, by the authors of the paper, been detected in five localities only, namely, Lamlash (Holy Isle) near Arran, the Beal near Portree in Skye, Gribun and Sorne in Mull, and Screpidale in Raasay. Basalt glass is always found in the Hebrides as a selvage to dykes, though elsewhere it has been described as occurring under other conditions where rapid cooling of basaltic lava has taken place. Some of the varieties of basalt glass in the Hebrides differ from any hitherto described by their high specific gravity (2·8 to 2·9) and by their low percentage of silica (45 to 50). This basalt glass is frequently traversed by numerous joints; it is occasionally finely columnar, and sometimes perlitic in structure. From the acid glasses (obsidian) it is distinguished by its density, its opacity, its magnetic properties, and especially by its easy fusibility, from which the name of tachylyte is derived. By its greater hardness it is readily distinguished from its hydrated forms (palagonite, &c.). In its microscopic characters basalt glass is found to resemble other vitreous rocks; thus it exhibits the porphyritic, the banded and fluidal, the spherulitic, and the perlitic structures. In the gradual transition of this rock into basalt, all the stages of devitrification can be well studied. The difference between these locally developed basalt glasses and the similar materials forming whole lava-streams in the Sandwich Islands was pointed out in the paper, and the causes of this difference were discussed. It was argued that the distinction between tachylyte and hyalomelane, founded on their respective behaviour when treated with acids, must be abandoned, and that these substances must be classed as rocks and not as mineral species; the name basalt glass was adopted as best expressing their relations to ordinary basalt, the term tachylyte being applied to all glasses of basic composition and being used in contradistinction to obsidian.—On a section recently exposed in Baron Hill Park, near Beaumaris, by Prof. T. G. Bonney, F.R.S., Sec.G.S. The author, about three years since, observed some imperfect exposures of a felsitic grit in the immediate vicinity of the normal schists of the district in a road which leads from Beaumaris cemetery to Llandegfan; but last summer had the opportunity, through the courtesy of Sir R. B. Williams, of examining the cuttings made in constructing a new drive, which runs through Baron Hill Park, very near the above outcrops. After tracing the normal schists along the steep scarp of the hill, he came, after an interval of about 60 yards, covered by soil and vegetation, to a massive gray grit consisting of quartz, felspar, and minute fragments of compact felsite, which now and then attain a larger size, being an inch or so across. These grits, which pass occasionally into hard compact mudstones (probably more or less of volcanic origin), can be traced for some 350 yards to the neighbourhood of the above-mentioned road, which is crossed by a bridge; and a short distance on the other side of this is a considerable outcrop of the grit, which in places becomes coarsely conglomeratic, containing large fragments of the reddish quartz-felsite so common on the other side of the straits, in the beds at or below the base of the Cambrian series. The schists appear to dip about 20° E.S.E., the grits about 25° E. The author, after describing the microscopic structure of the various rocks noticed, pointed out that this section, though the junction of the two rocks is probably a faulted one, has an important bearing on the question of the age of the Anglesey schists, micaceous and chloritic. The Survey regards them as altered Cambrian; it has even been suggested that they may be of Bala age; others have regarded them as Pebidian. Now the felsitic grits and conglomerates cannot be newer than the Cambrian conglomerate of the mainland, regarded by Prof. Hughes as the base of the true Cambrian, and are probably older, corresponding with some part of the series between it and the great masses of quartz-felsite which are developed near Llyn Padarn and Port Dinorwig, which series lithologically and stratigraphically corresponds with the typical Pebidian of Pembrokeshire. Hence, as the Anglesey schists are in the full sense of the term metamorphic rocks, and the "Pebidian" but slightly altered, this section shows that the former must be much older than the latter, and so be distinctly Archæan.—On the rocks between the quartz-felsite and the Cambrian series in the neighbourhood of Bangor, by Prof. T. G. Bonney, F.R.S., Sec.G.S. This district has already been the subject of papers by the author (*Quart. Journ. Geog. Soc.*, vol. xxxiv. p. 137), and by Prof. Hughes (vol. xxxv. p. 682), who differs from him in restricting the series between the quartz-felsite and Cambrian conglomerate to little more than the bastard slates and green breccias of Bangor mountain. The author has traced on the south-east side of the Bangor-Caernarvon road a well-marked breccia containing fragments of purple slate mixed with volcanic materials, below the above-named Bangor series, for more than a mile. At a lower level he has traced another well-marked breccia, chiefly of volcanic materials, for half a mile; and, lastly, a grit and conglomerate, apparently resting on the quartz-felsite named above, composed of materials derived from it. This has been traced on both sides of the road mentioned above for nearly two miles. For these and for other reasons given in the paper, the author is of opinion that, as he formerly maintained, there is a continuous upward succession on the south-east side of the road, from the quartz-felsite at Brithdir to the Cambrian conglomerate on Bangor mountain. The district on the north-west side of the road is so faulted that he can come to no satisfactory conclusions. The author is in favour of incorporating the above-named quartz-felsites with the overlying beds as one series, corresponding generally with the Pebidian of South Wales; older than the Cambrian, though probably not separated from it by an immense interval of time. An analysis of the Brithdir quartz-felsite by Mr. J. S. Teall, was given, from which it appeared that the rock corresponds very closely with the "devitrified pitchstone" of Lea rock in the Wrekin district, described by Mr. Allport, but differs considerably in composition from those in the Ordovician rocks of North Wales.

EDINBURGH

Royal Society, May 21.—Mr. Robert Gray, vice-president, in the chair.—Obituary notices were read of Sheriff Hallard, Dr. John Muir, Friedrich Wöhler, Sir J. Rose Cormack, M.P., and Dr. Morehead. Mr. John Aitken, in a note on the moon and the weather, observed that the phenomenon of the old moon in the new moon's arms was not always visible in a very clear atmosphere, but that other meteorological conditions seem to be requisite. He suggested that the earthshine might be greatly intensified by a cloud-laden atmosphere to the west of the observer.—Mr. D. B. Dott read a paper on the acids of opium, in which he stated that, contrary to the general opinion, the principal acid in opium, judged by its acidifying powers, is sulphuric and not meconic acid, a considerable portion of the

morphia being always combined with the sulphuric acid.—Prof. Tait gave some results of direct observations of the effect of pressure on the maximum density-point of water. The experiments were a modification of the well-known Hope experiment. A glass vessel of water with a self-registering thermometer at the bottom and a mass of ice at the top was placed inside the water (at 50° F.) of the large hydraulic press. Under a pressure of 3 tons weight per square inch, the thermometer fell to 33° F., whereas at the ordinary atmospheric pressure, but under otherwise similar circumstances, the temperature registered never fell below 41° F.

PARIS

Academy of Sciences, May 21.—M. E. Blanchard, president, in the chair.—Observations of the small planets made with the large meridian of the Paris observatory during the first quarter of the year 1883, communicated by M. Lœwy.—On the critical point of soluble gases, by J. Jamin. The critical point is defined to be the temperature at which a liquid and its saturated vapour have the same density. At and beyond this point the fluid and vapour become fused in one, and all latent heat disappears.—Extract from a memoir on the composition of combustible mineral substances, by M. Boussingault. The proportions are given of the carbon, hydrogen, oxygen, and nitrogen contained in the substances analysed—the bitumen of the Chinese fire-pits and Dead Sea, the Egyptian asphalt, fossil resins, and the anthracites and other coals of South America and France. A method is proposed for eliminating the hydrogen, oxygen, and other impurities from graphite, and thus reducing it, like the diamond, to pure carbon.—The scientific expedition of the *Ta'isman* to the Atlantic Ocean, by M. Alphonse Milne-Edwards. The *Talisman* sailed from Rochefort on June 1, and will visit the Canaries, Cape Verd Islands, Azores, and intermediate waters.—On the discussion recently raised by the Commission of the Turin Veterinary School, touching the state of the blood of a sheep subjected to carbonic vaccination when examined within a few hours of death and the day after death, by M. Pa teur.—Note by Admiral Pâris accompanying the presentation of his work on the "Naval Museum in the Louvre."—A new method of synthesis for the alkylnitrous acids, by G. Chancel.—On the part respectively played by oxygen and heat in attenuating the carbonic virus by the method of M. Pasteur, by M. A. Chauveau.—On the treatment of the water used in wool-washing, by MM. Delattre. This water yields 4·50 per 100 of a very dry potassium, or a total of 270,000 kilograms, valued at 4300*l.*, on the 6,000,000 kilograms of wool annually washed in France. But from this must be deducted 1000*l.* for the cost of treatment.—On the algebraic functions of Fuchs, by M. H. Poincaré.—On the theory of Euler's integrals, by M. Bourguet.—On the resistance of the atmosphere in very slow oscillatory movements, by M. J. B. Baille.—On the deformation of polarised electrodes, by M. Gouy.—On the electrodynamic interference of alternant currents, by M. A. Oberbeck.—On the sesquisulphuret of phosphorus, by M. Isambert.—On some double salts of lead, by M. G. André.—On the solubility of strychnine in acids, by MM. Hanriot and Blarez.—On a saccharine substance extracted from the lungs and phlegm of consumptive patients, by M. A. G. Pouchet.—On a deposit of quaternary mammals in the neighbourhood of Argenteuil (Seine-et-Oise), by M. Stan. Meunier. Here the author recently discovered remains of the elephant, *Rhinoceros tichorhinus*, cave hyæna, horse, reindeer, and a member of the ox family, apparently *Bison priscus*.—Vegetation of the vine at Calèves, near Nyon, Switzerland, by M. Eugène Risler.

June 4.—M. Blanchard in the chair.—The following papers were read :—On the possibility of increasing in a great measure the precision of the observations of the eclipses of Jupiter's satellites, by A. Cornu.—On the solubility of sulphide of copper in alkaline sulphomolybdates, by M. Debray.—On the solution of certain problems of cosmography by means of graphic tables, by MM. Lalanne and Ed. Collignon.—M. A. Caligny presented to the Academy his work entitled : "Theoretical and Experimental Researches concerning the Oscillations of Water, and the Hydraulic Machines with Oscillating Liquid Columns."—On recent scientific results obtained regarding the etiology of and preventatives from cholera, by A. Fauvel.—Researches on typhoid fever in Paris during the period October 19, 1882, to May 15 a.c., by M. de Pietra-Santa.—On an apparatus for obtaining low temperatures which can be graduated at pleasure, by P. Gibier.—On the hyposulphides of phosphorus, by M. Isambert.—On the sesquisulphide of phosphorus, by G. Lemoine.—Reply to M. le Goarant de Tromelin regarding the electric log, by M. Fleuriais.—On glass-blowing by means of mechanically-compressed air, by M. Appert.—On the observations of Brooks-Swift comet (*a* 1883) made at Paris Observatory, by G. Bigourdan.—On the development of the perturbating function, by B. Baillaud.—On the uniform functions of two analytical points which are left invariable by an infinity of rational transformations, by M. Appell.—On uniform functions, by J. Farkas.—On a correction of the stereotyped formula in the preface of Callet, by M. Em. Barbier.—Practical rules for substituting certain closed curves for a given arc, by H. Léauté.—On passive mechanical power, interior resistance, and other points relating to electro-magnetism, by G. Cabanellas.—On the freezing point of acid solutions, by F. M. Raoult.—Comparison of the evaporation of fresh water and sea water at different degrees of concentration ; consequences relating to a sea in the interior of Algeria, by M. Dieulafait.—Notes on the preceding communication, by M. Jamin.—Thermical studies on the solution of hydrofluoric acid in water, by M. Guntz.—On the transformation of glycol into glycolic acid, by M. de Forcrand.—Researches on the production of crystallised borates in the wet way, by A. Ditte.—On the reaction of sulphide of lead upon metallic chlorides, by A. Levallois.—On the burning of gypsum, by H. le Chatelier.—On an acid resulting from the oxidation of strychnia, by M. Hanriot.—On the life-capacity of the monstrous embryos of chickens, by M. Dareste.—On the artificial production of the inversion of the viscera or "heterotaxy" in chicken embryos, by MM. Hermann Fol and St. Warynski.—Observations on blastogenesis and alternating generation in Salpa and Pyrosoma, by L. Joliet.—On the localisation of virus in wounds and on the mode of its dissemination in the organism, by G. Colin.—Experimental researches on the lesion of the spinal marrow, determined by the hemisection of that organ, by E. A. Homén.—On the mechanical organisation of the pollen-grain, by J. Vesque.—Note on the life and work of Prof. da Costa Simoïdes of Coimbra, by Eduardo Abreu.—On a method of utilising sewage water, by MM. Delattre and Pinot.

"THE NEW PRINCIPLES OF NATURAL PHILOSOPHY"

The New Principles of Natural Philosophy. By W. L. Jordan, F.R.G.S. (London: David Bogue, 1883.)

IN the Preface to this large and handsome volume we are told that "The Third Chapter, ... and more especially the first nine Parts of that chapter, are the justification for the title of this work." This sort of intimation is unusual, but timely and useful, as it enables us to go at once to the root of the m tter, and to study "*The New Principles*" in themselves, before we commence the perusal of the formidable array of arguments, examples, and demonstrations which constitutes the bulk of the volume. The chapter referred to is formally dedicated to the memory of Descartes and Newton, "as it shows the connexion between the Cartesian Vortices and the Newtonian Laws (*sic*) of Gravitation."

The peculiar employment of the definite article in the title of the work at once arrests the attention of the reader. New principles in Natural Philosophy, some of them coextensive with our whole knowledge of the subject, have been happily introduced even in comparatively recent times. The Conservation of Energy, and Carnot's principle of Reversibility, are notable examples. But such principles consist of generalisations of our former knowledge, or additions to it, and are in no way subversive of the fundamental Laws of Motion (or *Axiomata*) as they were systematized by Newton.

"*The New Principles*," however, are not of this class. They involve, essentially, somewhat extensive modifications of Newton's Laws, and the consequences we have been accustomed to draw from them. So far as we understand our author, he seems to allow that Newton and his followers have correctly deduced the consequences which follow from the assumption of the Laws of Motion and the principle of Gravitation. But the accordance of the results, so deduced, with observed facts is a remarkable coincidence only:—arising from a compensation of errors, where incorrect ideas as to the laws of motion are rectified (so far as results go) by an omission of some of the more powerful causes which are really at work. Thus the true statement of the First Law of Motion is that a body gradually comes to rest when the motive force ceases to act; while "Gravitation is merely the act by which the material universe resists, or endeavours to resist, the motive forces acting on it. And, therefore, if matter were not inherently inert there would be no such force as gravitation" (pp. 306-7). It follows, of course, from the new principles that some cause, hitherto not taken into account, is required to explain the persistence of the earth's rotation and of its revolution in its orbit. Of course this cause must suffice for the same results in the case of each planet; and it must also maintain the rotation of the sun itself. This is found in "Astral Gravitation." How so immensely effective a factor in all the physics of the universe has hitherto been entirely overlooked it is not for us to say. We content ourselves with a humble effort to disseminate "*The New Principle*" as widely as our circulation permits, if not as widely as its intrinsic importance demands. We would merely premise that our author distinctly points out that, after all, Astrology was wrong only because its votaries recognised "personal influences," whatever these may be, and not the gigantic physical forces exerted on us and our surroundings by the stars:—

"Reason also tells us that whatever the apparent magnitude of any given star may be, the greater its actual distance from the earth, the greater is the force which it exerts on the earth; and therefore the argument that the stars are too far off for their power to be felt, even if it merit the designation of common sense, is absolutely refuted by reason.

"It is not possible in the present state of knowledge to make a reliable (*sic*) estimate regarding the actual force exerted by any star.

"Sir William Herschel assures us that the star Capella has an apparent diameter of 2½ seconds. Its distance as indicated by parallax is 4½ million times greater than that of the sun.

"Accepting these measurements as accurate, and supposing Capella to be of the same density as the sun, the force of gravitation which it exerts on the earth is equal to one hundredth part of that exerted by the sun. If, however, any star of equal apparent magnitude whose distance is so great as not to be indicated by parallax, be as many times more distant than Capella as Capella is more distant than the sun, then the force exerted on the earth by that star, according to the foregoing measurements, would be 45,000 times greater than that exerted by the sun."

"It is argued that none of the stars can have so great an apparent diameter as asserted by Herschel, because Huygens has estimated that the sun gives us 2,000 million times more light than we receive from Capella, and this, supposing the two bodies to be of equal brilliancy, would make Capella much smaller than estimated by Herschel. For a star of the apparent size estimated in this manner to exert as much force on the earth as is exerted by the sun, its distance would have to be 20 million times greater than the actual distance of Capella as indicated by parallax.

"Neither of these estimates can be regarded as better than vague guesses at the real size of the stars; but when, on the one hand, we consider the evidence which seems to necessitate the existence of some great controlling force of gravitation far distant from our solar system, and, on the other hand, the fact that the laws of optics and of gravitation make it quite possible that some one of the visible stars may actually be exerting a force far more than sufficient for the purpose indicated, reason is almost forced to the conviction that stars of the requisite magnitude do exist in the heavens."

How this, and "The" other "New Principles" account for Trade Winds, Ocean Circulation, Comets, The Zodiacal Light, The Secular Acceleration of the Moon's Motion, &c., must be learned from an attentive perusal of the work itself. The careful reader will have an ample and varied treat; for mixed with these weighty contributions to science, we have full details of a more strictly human character, such as "Replies to Critics," "Remarks on the Admiralty Current Charts," "A Public Challenge to the Council of the Royal Society," &c. We quote (from p. 365) a few words to show how very serious indeed is the state of matters with our great scientific Society.

"I last year publicly challenged the leaders of the scientific world in London to open discussion; and, in the second of the public lectures I then gave, I made it clear that the question at issue had ceased to be merely a

question of scientific opinion but had become also one of honour. And until the Council of the Royal Society take measures to refute or to atone for (!) the charges I then made, it is evident that courtesy and chivalrous conduct are at a discount in the scientific world, and it is not surprising that the deterioration of the tone of thought should be such as to have at length attracted the attention of the editor of the *Times*."

At p. 486 we have again the old question of the moon's non-rotation about its axis. This latest follower of Mr. Jellinger Symons gives a new and rather amusing argument in support of the heresy. For he says it would require us to suppose that a ship which sails round the world must have turned a complete somersault, while it is quite obvious that she has not done so!! Here we fear we must part company with our amusing instructor; and, though to many it may appear the blackest ingratitude, we must conclude with a hearty wish that Mr. Jordan's work had been published some twenty years sooner. Had it been then given to the world it would, like a fly in amber, have secured immortality in the pages of De Morgan's unique, because inimitable, *Budget of Paradoxes*.

It has many of the distinctive charms of the celebrated works of Mr. James Smith (of Liverpool), Mr. James Reddie, and Baron von Gumpach. All these great men, in their turn, tilted at Philosophers or Scientific Bodies, the Astronomer-Royal, the Royal Society, the British Association, &c., and complained, as Mr. Jordan now does, of the bigotry and malevolence in high places which depreciated the value of the gifts they were bestowing on the world. Some of them were hopelessly illogical and stupid, others merely ignorant. Mr. Jordan appears to belong to the second category. He is evidently untaught, though presumably not unteachable. But he should not attempt to teach.

P. G. T.

THE BRITISH MUSEUM CATALOGUE OF BATRACHIA

Catalogue of the Batrachia gradientia s. caudata, and B. apoda in the Collection of the British Museum. Second Edition. By G. A. Boulenger. (London: By Order of the Trustees, 1882.)

THIS volume completes the second edition of the Catalogue of the Batrachians in the British Museum. The former volume, which appeared in the spring of last year, we have already noticed. The first edition (1850) was prepared by Dr. J. E. Gray, and contained descriptions of 72 species; 132 species are described in the present work, the great majority of which have been actually examined by Mr. Boulenger. The number of species of tailed Batrachians in the British Museum collection now amounts to 78 against 38 in 1850. Several of the species which are wanting in the collection are natives of America, and in the interests of science we hope some of the distinguished herpetologists of the New World will generously supply these desiderata. The number of footless Batrachians in the Collection is 19 against 5 in 1850, and in this group also nearly all the species unrepresented in the national collection are natives of America. In addition to very full synopses of the families and subfamilies, of detailed diagnoses of the genera and species with synonyms, we have appended to this volume a summary of the principal facts of the geographical distribution of Batrachians generally, which adds immensely to the value of this catalogue to the general biologist. Of the various primary geographical divisions which have been proposed, Mr. Boulenger finds that that recognised by Dr. Günther for freshwater fishes into Northern Equatorial and Southern Zones, agrees best with the facts deducible from the study of Batrachians, but with one modification, for a Southern Zone does not exist for Batrachians. Tasmania and Patagonia do not differ in any point regarding their frog-fauna from Australia and South America respectively. The following are the principal conclusions:—(1) In the Northern Zone there is an abundance of tailed and an absence of footless forms. A. In the Old World division (Europo-Asiatic or Palæarctic Region) there are numerous Salamandrinæ, with a single exception an absence of Hylidæ, but Discoglossidæ are present. B. In the North American division we find Sirenidæ, few Salamandrinæ, Plethodontinæ, Amblystomatinæ, and Hylidæ numerous, Desmognathinæ. (2) In the Equatorial Southern Zone there is an absence of tailed Batrachians and an equally characteristic presence of footless forms. Dividing (A) the Old World region into Indian and African, we find in both the frogs numerous (260 species out of 300), an absence of Hylidæ and Cystignathidæ, while in the former there are no Aglossæ or Dendrobatidæ, while in the latter there are Dactylethridæ or Dendrobatidæ. Dividing (B) the New World region into Tropical America and Australia, the former is rich in footless forms (21 species), has very many tailless forms, some small families quite peculiar to the region, but above all is it rich in the Arcifera, it has also a few tailed forms; the latter is divided into three subregions: the Australian proper is chiefly remarkable for a negative character, there are no footless or tailed forms, almost no toads or frogs, its fauna consisting mainly of the two families, Cystignathidæ and Hylidæ; the Austro-Malayan subregion presents an interesting blending of Indian and Australian forms, a curious fact is the occurrence, according to Peters, of a third species of the African genus Phrynomantis in Amboyna and Batavia, New Caledonia does not yield a single Batrachian; the third or New Zealand subregion possesses but a single species, *Liopelma hochstetteri*, very curiously a member of the family Discoglossidæ, which is otherwise restricted to the Europo-Asiatic region. The following new species are described for the first time, and there are excellent illustrations of most of them in the plates accompanying this volume: *Hynobius peropus*, China and Japan, *Spelerpes yucatanicus*, Yucatan, *Uræotyphlus africanus*, West Africa, *Hypogeophis guentheri*, Zanzibar, *Dermophis albiceps*, Ecuador, and *Chthonerpeton petersii*, the Upper Amazon.

The keeper of the Department of Zoology in the British Museum may be congratulated on the Batrachian collection having held pace with the progress made in this branch of science during the last thirty years.

OUR BOOK SHELF

The Cinchona Planter's Manual. By T. C. Owen. (Colombo: A. M. and J. Ferguson, 1881.)

FEW plants have been so fortunate or unfortunate in having so much written about them as the *Cinchonas*. Ever since their successful introduction into India, now

some twenty years since, the Cinchonas have had showered upon them books and pamphlets innumerable, and where we find such voluminous writings, it would be strange indeed were there not matter of varied quality, and some that could be dispensed with altogether. Mr. Owen's book is very complete in the several branches of Cinchona literature, facts gathered from various authentic sources, such as the works of Dr. King, Dr. Bidie, Mr. McIvor, and the reports of the Indian and Javan Governments, all of which are acknowledged by the author.

The book is divided into six parts, the first part being devoted to the physiology of plants, gathered, as we are told, from Church and Dyer's "How Crops Grow." The second part treats of the alkaloids, the species and varieties, to which a large space is given, and the next part on the choice of land, felling, clearing, weeding, planting, &c. In the fourth part manuring and harvesting are considered; and in parts 5 and 6 the diseases to which Cinchonas are liable, and the estimates of Cinchona planting are digested. In all these matters careful details are given.

The book no doubt will be very useful to Cinchona planters, more particularly the practical part. Its greatest fault, perhaps, is the extent of the book, numbering 203 pages, too voluminous for many planters to wade through; but on the other hand it appeals also to those who, though not actual planters, are interested in the progress of the Cinchona culture.

Kallos, a Treatise on the Scientific Culture of Personal Beauty and the Cure of Ugliness. By a Fellow of the Royal College of Surgeons. (London: Simpkin Marshall and Co., 1883.)

THE author desires his book to be taken seriously. He shows that good looks and manners have a commercial value, since those are more likely to succeed in obtaining the prizes of life who can make favourable first impre sions than those who cannot. The first start greatly depends on patronage, and obscure youths who have won wealth and position have almost always been helped by their good looks, good address, and good voice. These are aids of considerable importance to every candidate, whether it be for a place behind a counter or for the suffrages of a constituency. The author considers from a medical point of view how ill-favoured individuals may palliate their defects. He treats ugliness as a disease, classifying its various forms and indicating such remedies as he can. His classes are coarseness, thinness, obesity, vulgarity, wrinkles, defects of circulation, of complexion, and of the hair. Then he takes the features in detail, eyes, nose, mouth, &c. His recipes are not numerous. We learn incidentally that what is sold as lime juice and glycerine for the hair contains no glycerine at all, and that a very popular dressing is castor oil and rum. This would have harmonised with the toilette of the Syrian beauty of old times, whose "garments smelt of myrrh, aloes, and cassia," a very apothecary-like fragrance. The book does not contain practical advice of much novelty, but its interest chiefly lies in directing attention to much that we already know but are too apt to forget; such as that dissipation, gross feeding, and indolent ways create ugliness of various forms. We know there are bad schools where the boys are slouching, ill complexioned, furtive in expression, and generally ugly, and we also know that there are good schools where, owing to healthy habits and keen and varied interests, the boys are bright, vivacious. and attractive. Similar differences due to different habits of life exist in men; they are pre-eminently shown by the good effect of drill on a plough-boy or street lounger. We may be sure that those who habitually cultivate a healthy mind in a healthy body, and who study how to please, cannot fail to add to the total happiness of the world and to secure for themselves a better chance of succeeding in it than their more negligent rivals.

The Nat Basket. (Printed for the Editress and Publisher, Mrs. Eleanor Mason, at the Albion Press, Rangoon, Burmah.)

WE hope that the subscribers to this extraordinary publication are content to give to it their money and nothing more. It is designed, we are told, to show the natives that there is no contradiction between Scripture and science, but if they believe that what is presented to them in the *Basket* is science they are much to be pitied. Such a medley of misstatements, absurd etymologies, and false astronomy was never before met with out of Bedlam. If this is the stuff that is taught the Burmese by our missionaries, the sooner the latter return home the better.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts, No notice is taken of anonymous communications.*

[*The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to insure the appearance even of communications containing interesting and novel facts.*]

Deductive Biology

IN the few remarks which I communicated to this journal (vol. xxvii. p. 554) under the above heading, I protested against the deductive method used in a purely literary manner as a mischievous way of attacking biological problems. Mr. William White objects that if I am right the deductive method must be excluded altogether "as a false and dangerous element of philosophy." I do not myself see that this necessarily follows. The pith of what I said simply amounts to this—the biological sciences not having reached the deductive stage, it is not possible to enlarge our knowledge in them by mere ratiocination. This is I apprehend no more than is laid down by Mr. Mill himself. Writing of the conditions under which the deductive method is applicable, he expressly says that without one indispensable adjunct "all the results it can give have little other value than that of guesswork" ("System of Logic," 4th ed. vol. i. p. 498). The indispensable adjunct is verification, which requires the substitution of the work-table for the desk. When the former has put the stamp of confirmation on the speculations elaborated at the latter we get a scientific result which commands attention. Without this confirmation I am still of opinion that the deductive result is only "a literary performance." It is worth noting that the able writer whose papers and method I took the liberty of criticising so far admitted the validity of what I said, that he promised to have some experiments made which would go a considerable way towards demolishing or sustaining the results at which he had so far arrived only deductively.

As it would be a rather arduous undertaking to follow Mr. White over all the other ground covered by his letter, I will only refer to one point. He asks whether "comparative embryology" is not "founded entirely upon the method of deductive analogy." I am certainly myself under the impression that it would be difficult to pitch upon any area in science in which the knowledge we possess has been more conspicuously gained by persistent investigation or one in which generalisations have more often crumbled under the pressure of fresh results of observation. It is the section-cutter, and not the desk, which has won the victories in this field. At the present moment two of the most skilled of our younger embryologists (with funds furnished by the Royal Society) are on the point of starting, one for the Cape, to study the embryology of *Peripatus*, the other to make a similar attempt in Australia on the earliest phases of the life-history of *Ornithorynchus* and *Ceratodus*. They would hardly perhaps engage in so laborious a quest if it would answer equally well to stay at home with a ream of paper, and, say—without any disrespect to the eminent author—a copy of the writings of Mr. Herbert Spencer as "a base of fundamental truth" to start from in the analogical deduction of the embryology of these organisms.

W. T. THISELTON DYER

YOUR correspondent, Mr. William White, has not, it seems to me, a correct appreciation of the words "deductive" and

"induction," as used in reference to the investigation of the causes of phenomena. The mistake which he makes is a very frequent one, and is due to the ambiguity of the words themselves, and to the inaccessibility of a treatise on modern logic.

The "deductive method," as formulated by John Mill, is one method by which the mental process known as induction—"the operation of discovering and proving general propositions"—is accomplished. An "induction" may be a simple inference from an observation; it must be an inference in which the conclusion is *wider* or *more general* than the premises from which it is drawn. A "deduction" (as the term is commonly used) is a result of ratiocination solely, or, in other words, of a "train of reasoning," by which from a general proposition (not alone, but by combining it with other propositions), we infer a proposition of the *same* degree of generality with itself, or a *less* general proposition. The "deductive method" receives its name from the fact that ratiocination is combined in it with induction.

"In order to di cover the cause of any phenomenon by the deductive method, the process must consist of three parts:—(1) Induction; (2) Ratiocination; (3) Verification;" or in common language: (1) A generalisation from observed facts [or a deduction from a previous generalisation]; (2) A deduction from this generalisation [or from an initial deduction]; (3) The testing or verification of the final deduction.

The "hypothetical method" is a special and very usual form of the deductive method in which in place of an induction or primary deduction we have substitnted a hypothesis. Under proper safeguards this is the most valuable and fertile method of investigating the causes of complex phenomena. Hypotheses are legitimate or illegitimate. The cause suggested by the hypothesis, if not already known as existing, ought to be capable of being known, and, until the cause suggested is shown to exist, the hypothesis, although verified, constitutes only a plausible conjecture. Further, the hypothesis must be such that no other hypothesis substituted for it would lead to verification.

A hypothesis, as distinguished from a proposition resulting from a complete induction or a correctly formulated deduction, is "a supposition without actual evidence or with evidence avowedly insufficient." The whole value of a hypothesis lies in the final carrying through with it of the deductive method. It must be made the starting-point of deductions, and these must be (one or more) brought to the test of observation or experiment—the final process of verification.

So much by way of preliminary.

The objection which my friend Mr. Thiselton Dyer has made to the essay of Mr. Grant Allen upon the forms of leaves does not, it appears to me, consist in a depreciation of the "deductive method" as Mr. William White is led to believe. Nothing can be further from the real state of the case.

What Mr. Dyer objects to is that the method is *not carried out* by Mr. Allen. Mr. Allen gives us hypotheses—suppositions with insufficient evidence—and deductions from the generalisation of evolution, but he is relatively deficient in "verification." He also fails in the condition insisted on by Mill, who holds that the hypothetical method is valueless (or relatively so) unless it be proved that no other hypothesis than that formulated can be similarly verified. He further, in the case of the supposed exhaustion of the carbonic acid in atmospheric air, appears to fail in another respect indicated by Mill, in so far as he does not demonstrate the actual existence of the cause which he assumes in his hypothesis. His proposition on this head is no more than "a plausible conjecture" at the best, and is not a legitimate conclusion arrived at by the deductive method.

I do not think that there is any ground for discountenancing either a "purely deductive" or a "purely inductive" method in the treatment of biological topics, so long as the method is soundly and thoroughly carried out and its logical results truly and clearly stated. Still less is there any shadow of reason for not fully accepting *the* "deductive method" (so named) as the method of biological research. What we have to deprecate in some modern speculative essays is the tendency to put forward suppositions as though they were propositions which have been demonstrated, and to employ the printing press in launching hypotheses which are neither legitimate inductions nor deductions, and should be kept unpublished until their originator has thoroughly examined them by the accepted "deductive method."

The Peak of Teneriffe *not* very Active again

WITH reference to my notice in NATURE, vol. xxvii. p. 315, stating, on the authority of a native lady in Santa Cruz, that the Peak of Teneriffe was active again, even to the extent of exuding a red-hot lava stream from near its summit, I am informed now from a higher scientific authority, viz. a Cambridge man, and high Wrangler there in his day, but since then resident in Teneriffe, near Puerto Oratava, for fifty years, that that view was exaggerated. I hasten, therefore, to present to your readers exactly what this venerable and experienced man has to say, without altering a word, so far as the extract goes:—

"The facts of the case," says he, "are simply these. On a clear day of south weather, about the latter end of December or the beginning of January last, I happened to be looking at the Peak (as I often do) and observed several distinct and very copious gushes of steam issuing from the summit. In similar weather I had often seen a similar phenomenon, but never to anything like the same extent. I watched these steam gushes several times that day, and very remarkable they were. On going down to Port the following day, I found they had been seen by several people there, who declared that the peak was pouring forth volumes of smoke and flames. The so-called smoke was simply the steam gushes I have mentioned, and what were mistaken for flames I am convinced were nothing but the same steam gushes illumined by the rays of the setting sun. All agreed that after dark nothing was to be seen there, which certainly would not have been the case had there been fire or flames. As for the lava stream, *that* was a pure fiction of an excited brain. I have looked carefully at the Peak through my telescope, and see nothing but the old, black lava streams that I have known for the last fifty years, and I have spoken with one of the guides who has been lately with a party to the summit, and he declares he saw no trace of any eruption, or of anything different from what he has always seen there."

Then follow some other topics to the end of the letter proper; but to that there is appended the following P.S., which may be interesting to intending travellers this summer:—

"Last night (May 27), about an hour and a quarter after midnight, we had a smart shock of an earthquake which woke me out of a sound sleep and rather frightened us all. However, no damage was done, but here people say that eruptions of the volcano are always preceded by earthquakes; so who knows but that our eccentric friend's vision of the three bonfires and the lava stream may come to be verified after all. If the Peak has any intention of erupting again, *I* should be personally obliged to it if it would do so while I am still in the body. It would be a grand sight from our Sitio."

To any of the previously mentioned intending visitors to the island I would beg to recommend that they carry Dr. Marcet's recent neat little book on "Southern and Swiss Health Resorts." His descriptions of Teneriffe, and especially of Guajara on the great crater, and Alta Vista on the high peak, are graphic, and true though terse. Indeed the only point of difference I have with him is his reason for there not being forthwith erected a grand hotel on the elevated Canadas, high above the summer cloud level, in the driest air, strongest sunshine, and most curative conditions for the moist kinds of consumptive disease, which the whole of this planet world has to offer. The reason he gives is, that there is nothing to interest the invalids, or ordinary lady and gentleman travellers up there.

Yet there have long been mineralogy, geology, a peculiar, though scanty, botany, meteorology of a most commanding type, and astronomy under special advantages, inviting all the readers of NATURE to go there and participate in the mental feast; while now the probabilities each morning of witnessing from a distance a little real eruption, will add an exciting topic to the breakfast conversation and the noonday ramble.

"Devil on Two Sticks"

WHY a game at once so graceful and attractive should have received such a christening I do not know, and I am equally at a loss to imagine how an outdoor sport like this, requiring skill and promoting a healthful exercise of the muscles, should have passed out of sight and become almost forgotten. Like Clerk Maxwell, I have played the game many a time some twenty years since, and hasten without further preliminary to describe it.

Imagine two cones joined together at their small ends like an hourglass, and that a solid of such a shape and size is turned out of walnut or cherry or boxwood or of ebony or ivory: this is the devil. Now take the last half-yard from the taper ends of two billiard-sticks, and let them be connected from these ends by a limp silken cord or string half a yard long: these are the sticks.

To play the game hold the thick ends of the sticks one in each hand, bring the cord under the narrow neck of the solid and try to elevate it in the air: it drops directly on the grass. If a brisk rotary motion is given to it however, it will not only remain on the cord, but several dexterous manœuvres may be accomplished with it: the variety of which and the skill displayed in performing them constitute the game. To produce the revolutions the sticks are moved rapidly up and down alternately, and when the spinning is once established, "Diabolus" may be allowed to run up and down the stick, or he may be projected high up in the air, and, still spinning all the while, be caught on the cord again and again in rapid succession. Two may be engaged in the same game. It was fashionable many years since in these parts, and I recollect seeing a picture in a Tunbridge-ware shop in this place of the lords and ladies engaged in playing this game on the Pantiles at Tunbridge Wells more than half a century ago. JOHN GORHAM

Bordyke Lodge, Tunbridge, June 4

[This is a nearly complete answer to our correspondent's query. The behaviour of the "devil" is an excellent example of that property of the axis of greatest or least moment of inertia of a body which is utilised in a well-thrown quoit or an elongated rifle-bullet. The mode of producing the rotation is easy to learn by trial, but not very easy to describe. The sticks are kept moving so that one end of the cord is always at a greater tension than the other.—ED.]

Channel Ballooning

As I have shown in my pamphlet, "Les Grands Ascensions Maritimes," the British Channel is the proper field for trying maritime ascents and determining which are the best means for rendering balloons serviceable on sea as well as on land. I have had several conversations with Lhoste, my aëronautical pupil, on the circumstances of his audacious trip. I will confine myself to the scientific teaching of this expedition.

The cone anchor was lowered by Lhoste when he saw that the *Noëmi* was running after the balloon, and diminished so much the velocity of the run that it was possible to catch him with a rowing boat. But although the wind was rather mild, the balloon inclined so much that the car was plunged into the water, and the waves drenched the occupant. It is evident that in stormy weather the lowering of the cone anchor would lead to the destruction of the balloon by pressure of the wind. To avoid this it is necessary to reserve the cone anchor for ordinary winds, and to use in other circumstances guide-ropes with wooden nuts passed through them in order to increase friction as much as possible.

The balloon went to the great altitude of 15,000 feet through the activity of the sun, which can be resisted very easily by taking some litres of water out of the sea, when nearing it, with a very simple apparatus that Lhoste has invented.

Any balloon attempting to cross the Channel should be bound to take on board half a dozen carrier pigeons to indicate the place where it has anchored, or has been rescued or landed, so that help could be sent to it without any delay. With such easy precautions, and the throwing out of a sufficient number of pilot balloons, the experiments can be conducted on scientific principles, and exert the most useful influence on the study of aërial currents on these seas, where several such currents combine, and where the constitution of the air is so peculiar that mirages of every description have been frequently seen even at the present season.

Lhoste, on the morning of June 9, saw at an altitude of 1200 feet a regular halo, which surrounded the sun. The fog was so heavy that he could not see the sea, except when it was almost ready to send him to a watery grave. The steam whistling from vessels in different seaports, reached him at every altitude; but he did not know what was the cause of the extraordinary noise.

If it had not been for the fog, Lhoste would have succeeded in a scientific sport which will become fashionable, and ultimately lead astronomy to try the air, and to trust to the winds in spite of Shakespeare.

Lhoste's audacity seems to have given rise to a competition in the Mediterranean from Marseilles, but I believe that the Mediterranean must only be tried when the British Channel has been traversed without difficulty in every direction, and that this part of the ocean will play an important part in the development of aërial navigation in the second century of its existence.

Boulogne, June 17 W. DE FONVIELLE

Geology of Cephalonia

CAN any of your readers kindly inform me whether geological investigations were ever made in the island of Cephalonia, one of the Ionian Islands that were under British protection up to the year 1863?

The following are the names of the fossils that I have been able to determine out of those that were given to me and brought last year from Climatzias, Thermanti, and Leacas, localities in the neighbourhood of Mount Cephalos, in the island of Cephalonia:—

Mitra fusiformis, Brocc.	*Cerithium* ——
M. Bronni, Mich.	*Turritella turris*, Bast.
M. Michelotii, Hörnes.	*Turritella* ——
Buccinum costulatum, Brocc.	*Turritella subangulata*, Brocc.
B. prismaticum, Brocc.	*Vermetus intortus*, Lam.
Chenopus pes pelecani, Phil.	*Natica millepunctata*, Lam.
Triton Turbellianum, Grat.	*Natica* ——
T. corrugatum, Lam.	*Dentalium* ——
Murex spinicosta, Bronn.	*Venus multilamella*, Lam.
Murex ——	*V. plicata*, Gmel.
Murex ——	*Chama gryphoides*, Linn.
Fusus mitræformis, Brocc.	*Cardita Jouanneti*, Bast.
F. virgineus, Grat.	*Pectunculus pilosus*, Linn.
F. longirostris, Brocc.	*Limopsis calabra*, Seguenza.
Turbinella subreticulata, d'Orb.	

Bucuresti (Roumania), June 2 J. P. LICHERDOPOL

Lightning Phenomenon

WHILE watching the incessant play of vivid lightning during the progress of a thunderstorm which was raging close by in the country towards Novara, Arona being just on the northern limit, my wife observed the following curious spectacle, the account of which she wrote down immediately afterwards:—At 9.35 p.m. on Sunday, June 3, a meteor-like object was seen to pass apparently from south to north (window facing due east), coming from the side of the storm and disappearing behind a mass of cloud which capped the high hill of Monte Val Grande above Lago Varese. It was oblately spheroid in form and apparently about the size of a fire-balloon, and with the velocity of a rocket was travelling slowly, for it left no visible track. It was of a bright, clear, whitish yellow, with a bright, pale green colour showing on the northern side when it passed behind the dark cloud. It was about three times as high above the horizon as the low hills opposite Arona, and traversed an angle of 45° horizontally from the point where first seen to its disappearance. The next day (June 4) when visiting friends at the Villa Frauzosine, near Tutra, we ascertained that this meteor-like body had also been seen by two or three persons who were sitting on a terrace watching the brilliant lightning to the south; they observed it moving also from south to north, disappearing behind the mountains to the northward. Waterspout

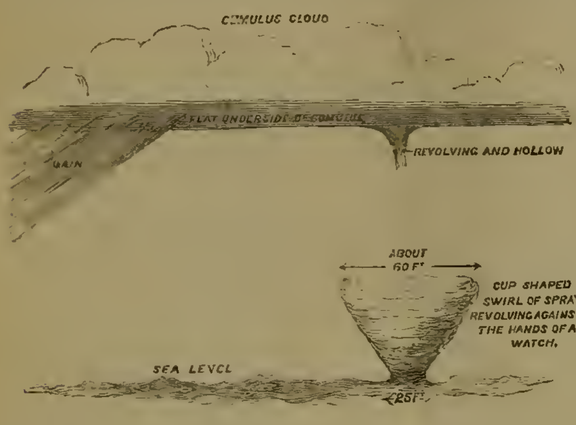
ON April 28 last the Cunard steamship *Servia*, in making her outward voyage to New York, fell in with several small waterspouts. Being on deck at the time I made a rough sketch and some notes of the occurrence, which I now venture to send you, having learned that many officers of these steamers have sailed the North Atlantic for years without having witnessed any similar phenomenon there. The ship's position may be easily deduced from the fact that her latitude was 42° 24′ and longitude 51° 3′ at noon on the 27th, while these were 41° 42′ and 59° 53′ respectively at noon on the 28th, at 8.30 a.m. of which day we met the waterspouts. There was hardly any wind at the time, and

the sky, which had been generally overcast, was rapidly breaking up into masses of cumulus clouds separated by wide spaces of blue. About a dozen waterspouts were seen in all, the ship passing right through one of them and thus enabling me to estimate its diameter by direct comparison with the known beam of the *Servia*.

The swirls of spray rose from the sea in a cup-like shape, and revolving rapidly in a direction opposite to that of the hands of a watch. It was only after such a swirl had become well defined that the lower surface of the cumulus cloud above it began to descend as if to meet it, spinning at the same time. Indeed, so inconspicuous was this feature of the phenomenon that many of the passengers, intent on watching the spray-cups sparkling brightly in the sunshine, failed to notice it at all. In no case did the cloud swirl nearly meet the sea swirl, nor did the double-



funneled stem of whirling mist, so generally shown in books, appear. Some spray fell heavily on deck from the swirl through which the *Servia* passed, but the wind, which struck us at one moment on this, at the other on that, side of the face was not brisk enough to carry off any one's hat. The sight was remarkably beautiful whether closely or distantly viewed. In the one case the spray-cup seemed made of rustling jewels which sparkled in the bright sunshine; in the other, the sea horizon appeared as if here and there set with boiling and steaming caldrons, whose rope-like handles hung from the dark undersides of white billowy clouds. Meteors of June 3

THE large meteor seen by Mr. Hall and others (NATURE, vol. xxviii. pp. 126, 150) was also observed here by Mr. Paul Mathews and myself. We estimated the length of its path while visible as 120° with the middle part due east, the direction of its motion as parallel to the horizon, elevation as 20°, and length of tail as 25°; its apparent brilliance I put at six times, Mr. Mathews at twice, the greatest brilliance of Venus, and the pieces into which it broke up (about six in number) as equal to the brightest planets. The time I should have put at 10.50, but did not note it (Mr. Mathews 10.40 to 10.45). The colour was golden. This was moreover in a very clear and brilliant sky, as about 10 we had observed that the light in the east was so intense that it cast quite a dark shadow as we passed through a somewhat shady part of the road.

Ripon W. W. TAYLOR

IN the correspondence on the large meteor seen on June 3 I have not seen any notice of another curious meteor seen later on the same night. A flash of light in the sky drew attention to it, and when first seen it was moving in nearly a straight line from 102 Herculis to α Aquilæ. In five seconds it travelled slightly more than half the distance to the latter star, and then disappeared without any outburst. It was about a lunar diameter in length, and between 3' and 4' wide at the widest part, a point distant one-third of its entire length from the head. In fact it was not at all unlike a comet with a bushy tail tapering off to a point. The colour was a pale yellow. P. F. D.

London, W.

Intelligence in Animals

SOME years since, when calling on the late Hon. Marmaduke Maxwell of Terregles, our conversation happened to turn on the subject of intelligence and instinct of animals. Mr. Maxwell said if I would walk down to the stables with him he would show me a curious instance. On reaching the stable he pointed out an empty stall in which five well grown young rats were running about—a board had been fixed at the end of the stall to prevent the rats getting out. Some time before the cat had a litter of five kittens, *three* were taken from her and drowned; the following morning it was found she had brought in *three* young rats, which she suckled with the two kittens that had been left; a few days afterwards the *two* kittens were destroyed, and the next morning it was found the cat had brought in *two* more young rats. While we were looking at this strange foster family the cat came into the stable, jumped over the board and lay down, when the rats at once ran under her and commenced sucking. What makes the matter the more singular is, the coachman told me the cat was a particularly good ratter, and was kept in the stable for the purpose of keeping down rats.

AMERICAN ETHNOLOGY[1]

UNDER the able management of Major J. W. Powell the Bureau of Ethnology, recently attached to the Smithsonian Institution, has already done much useful work in the wide field of American anthropology. This first annual report, however, of its proceedings for the year ending July, 1880, appears to be somewhat behind time for, although bearing on the title-page the date of 1881, it was not issued to the public till the beginning of the present year. But the delay is doubtless due to the large amount of preliminary work required to be got through in organising the department, and future reports may be expected to appear more punctually. The title, "Annual Report," is itself somewhat misleading, the actual report of the director really occupying no more than thirty-three introductory pages, and consisting mainly of a digest of the rich materials filling a large quarto volume of over 600 pages. Hence this is, strictly speaking, a first volume of the *Proceedings* or *Transactions* of the Bureau, and as such gives fair promise of a long and useful career in an anthropological domain which may be regarded as practically unlimited.

From the director's introductory remarks we gather that, after the fusion in 1879 of the various geological and geographical surveys in the general "United States Geological Survey," the Bureau of Ethnology was created and attached to the Smithsonian Institution for the purpose of continuing the anthropological work which had hitherto been prosecuted in a somewhat desultory way by those Surveys. The management of this newly-organised department was intrusted to Major Powell, who, as former Director of the Survey of the Rocky Mountain Region, had already shown special aptitude for ethnological investigation. The direct object of the Bureau, we are told, is to systematise anthropological research in America, and this it is proposed to effect both by the prosecution of research through the direct employment of students and specialists, and by the general encouragement and guidance of original observers co-operating throughout the continent. "It has been the effort of the Bureau to prosecute work in the various branches of North American anthropology on a systematic plan, so that every important field should be cultivated, limited only by the amount appropriated by Congress" (xiv.).

How closely this wide programme has been so far adhered to is evident from the varied contents of this

[1] "First Annual Report of the Bureau of Ethnology, Smithsonian Institution, 1879-80." By J. W. Powell, Director. (Washington Government Printing Office, 1881).

sumptuous volume, which comprises sundry contributions by the director on the "Mythology of the North American Indians," on the "Evolution of Language," on "Wyandot Government," and on "Limitations to the Use of some Anthropological Data"; a valuable and profusely illustrated treatise on the "Mortuary Customs of the North American Indians," by H. C. Yarrow; a preliminary attempt to decipher "Central American Picture Writing," by E. S. Holden; a paper by C. C. Royce on "Cessions of Land by Indian Tribes to the United States;" Col. Garrick Mallery's important treatise on "Sign Language among North American Indians," which has already appeared as a "Separat-Abdruck"; a "Catalogue of Linguistic MSS. in the Library of the Bureau of Ethnology," by J. C. Pilling; lastly, "Illustrations of the Method of Recording Indian Languages from the MSS. of Major J. O. Dorsey, A. S. Gatschet, and S. R. Riggs." Should the department continue to be administered on these broad lines and in this enlightened spirit, a school of anthropology must soon be developed in America, with which, without liberal State subvention, our European societies will find it difficult to keep pace. But with our petty rivalries, our heavy public burdens and constantly increasing armaments, the prospect of such State subvention seems at present at least somewhat remote.

The papers contributed by the director to this volume touch briefly on several important topics of a general character, and often express views regarding the origin and evolution of speech, mythologies, religious and tribal institutions, which will scarcely go unchallenged in some quarters. That these psychological phenomena have hitherto been studied from a somewhat too subjective standpoint, and that many metaphysical subtleties have consequently been grafted on the theogonies and early philosophies of savage man may readily be admitted. In a paper on the mythology of the Indian Aryans recently read before the English Folk-Lore Society, Mr. Andrew Lang dwelt on the necessity of distinguishing between the old and comparatively modern hymns in the Vedas. He pointed out that the Vedas themselves do not embody the most primitive theories on the origin of man and the universe, that they contain ideas at once very old and very new, very mythological and very philosophical, and he adduced several instances of crude and childish savage myths overlapping the more profound and advanced concepts of the Aryan Hindus. In the same way Major Powell argues that philosophy passes in its upward evolution through two stages—the mythologic, in which all outward phenomena are interpreted by analogy with subjective experience, and the scientific, in which they are treated as orderly successions of events. The mythologic necessarily precedes the scientific stage, for "without mythology there could be no science, as without childhood there could be no ultimate forms." It follows that the views of primitive men are simple, childish, and incoherent, and that it is illogical to credit his theogonies, as is often done, with profound and abstruse concepts of the universe. Here, as in all other evolutions, the progress is from the simple and homogeneous to the complex and heterogeneous; the "unknown known" of savage philosophy antedates the "known unknown" of later science. In the primitive stage all things are known, that is, supposed to be known; later on some few things are really discovered, and these when properly understood throw doubt on all the rest. The era of the known unknown is thus reached; to crude and offhand explanations succeeds the critical period of investigation and discovery; science is born; civilisation begins. This upward growth is illustrated by many examples, such as that of the rainbow—which for the Shoshoni (Snake Indian) is a beautiful serpent abrading the icy firmament to give us snow and rain; which in the Norse myth is the bridge Bifrost stretching from earth to heaven; which in the *Iliad* becomes the Goddess Iris, Messenger of Olympus; in Genesis a witness to the Covenant; in science an analysis of white light into its constituent colours.

North America, it is aptly remarked, presents a magnificent field for the study of savage and barbaric philosophies from this fresh standpoint. Formerly attention was paid almost exclusively to the more advanced peoples, Aryans, Semites, Hamites, Chinese. Now it is felt that the complex mythologic, religious, linguistic systems of these peoples are the outcome of earlier and simpler phases of thought, consequently that the study of barbarous and savage communities can no longer be neglected. But in North America alone we have our seventy-five ethnical groups speaking seventy-five stock languages and more than five hundred well-marked dialects, each linguistic stock with a philosophy of its own, or rather as many philosophic systems as it has distinct languages and dialects.

To account for this astounding diversity of speech, Major Powell holds with one or two distinguished European philologists that the fundamental languages must have been evolved in independent centres, that in fact "mankind was widely scattered over the earth anterior to the development of articulate speech, and that the languages of which we are cognisant sprang from innumerable centres as each little tribe developed its own language" (p. 28). He fails to see that this view, in itself to the last degree improbable, is wholly unnecessary and even inadequate to explain the actual conditions. It is unnecessary because the present diversity of speech may be sufficiently accounted for by its vast antiquity and extremely evanescent character. Time, acting in combination with the phonetic growth and decay inherent in all speech, must inevitably effect an indefinite amount of specific change, even supposing that all languages started from a single centre. No evolutionist can deny this, for he admits that time combined with a tendency to modification in altered environments, has brought about an indefinite amount of specific and generic change in the biological world. But animals and vegetables are certainly more persistent, *cæteris paribus*, than linguistic types. *Ergo*. The theory is moreover inadequate to explain the actual conditions in America alone. Here we have doubtless a vast number of specifically distinct languages; but the mechanism of all is very much alike; all are cast, as it were, in the same mould; all belong to the polysynthetic or at least to the agglutinating order. But if speech had in America been evolved in many different centres, it may be asked how this striking uniformity is to be explained? Why have we not here, as elsewhere, representatives of the isolating[1] and inflecting, as well as of the polysynthetic order of speech? Does not their common structure point at a common centre of dispersion, while their specific diversity within this common groove is amply explained by time and evanescence?

But if Major Powell does not always reason conclusively, he is a good observer, and describes in vivid language the scenes of savage life of which he has been a spectator, as witness the subjoined account of oral narrative in the Indian community:—

"On winter nights the Indians gather about the campfire, and then the doings of the gods are recounted in many a mythic tale. I have heard the venerable and impassioned orator on the camp-meeting stand rehearse the story of the crucifixion, and have seen the thousands gathered there weep in contemplation of the story of divine suffering, and heard their shouts roll down the forest aisles as they gave vent to their joy at the contemplation of redemption. But the scene was not a whit

[1] The Othomi of the Anahuac tableland has been cited as an instance of an isolating language in America. But M. de Charancey rightly regards Othomi rather as "une langue primitivement incorporante [polysynthetic], qui, parvenue au dernier degré d'usure et de délabrement, a fini par prendre les allures d'un dialecte à juxtaposition [isolation] ("Mélanges de Philologie," &c., p. 80, Paris, 1883).

more dramatic than another I have witnessed in an evergreen forest of the Rocky Mountain region, where a tribe was gathered under the great pines, and the temple of light from the blazing fire was walled by the darkness of midnight, and in the midst of the temple stood the wise old man, telling in simple, savage language the story of *Ta-wdts*, when he conquered the sun and established the seasons and the days. In that pre-Columbian time, before the advent of white men, all the Indian tribes of North America gathered on winter nights by the shores of the seas, where the tides beat in solemn rhythm, by the shores of the great lakes, where the waves dashed against frozen beaches, and by the banks of the rivers flowing ever in solemn mystery—each in its own temple of illumined space—and listened to the story of its own supreme gods, the ancients of time" (p. 40).

A detailed notice of the other more important papers in this volume must be reserved for a future occasion.

A. H. KEANE

THE FISHERIES EXHIBITION

WE are gratified to see the very thorough way in which the management of the Fisheries Exhibition are endeavouring to carry out their plans. It is evident that the scientific aspects of the wide and important subject will have a fair amount of attention; and we are glad to think that in this direction advice has been sought in the right quarter. In the Exhibition itself those interested in the science of the subject will find much to attract them. Last week (p. 156 we gave a list of subjects which have been settled for conferences, and among those who have consented to read papers, we find such names as Professor Huxley on Fish Diseases, Professor Ray Lankester on the Scientific Results of the Exhibition, Professor Brown Goode on the Fisheries of the United States, Professor Hubrecht on Oyster Culture and Fisheries, Sir Henry Thompson on Fish as Food, Dr. F. Day on the Food of Fishes, Mr. R. H. Scott on Storm Warnings. Further, we are glad to see that a series of handbooks has been arranged for on subjects cognate to the Exhibition. Among them are a few by men of scientific standing, and likely to be of real scientific importance; we hope it may not yet be too late to secure the preparation of a few more handbooks or reports of a similar character. Among the handbooks arranged for, six will be published this month, and the remainder in July. Those of special interest to science are, "The Life History of Fishes," by Prof. H. N. Moseley; "Fish Culture" and "Indian Fish and Fishing," by Dr. Francis Day; "Food Fishes," by Mr. G. B. Howes; "Marine and Freshwater Fishes of the British Isles," by Mr. Saville Kent; "Curious Sea Creatures," by Mr. Henry Lee.

The conferences were introduced on Monday by an interesting lecture by Prof. Huxley, a report of which we give below, and this was followed on Tuesday by a carefully prepared paper by the Duke of Edinburgh, on British Fisheries and Fishermen, read by the Prince of Wales. The real interest which the leading members of the Royal family take in the Exhibition has no doubt done much to contribute to its success. It was to be expected that the German Ambassador would show his appreciation of the importance of science to an industry of such magnitude as that of fishing, and he aptly pointed out how important was the didactic and scientific work at last commenced.

With the general concurrence of opinion in high quarters as to the value of the scientific aspects of the Exhibition, and of the great services which science may render in bringing about the practical objects which are aimed at, we of course heartily concur. It is admitted on all hands that the haphazard way in which our fisheries have hitherto been carried on has led to the worst results, the extinction almost of some important fishes and mollusks, the bad condition of others, and the dearness of what might be the cheapest and most plentiful of foods. In recent years science has done something to remedy this state of things, and it will be well for our fisheries, and therefore for the welfare of a large portion of our population, if the Fisheries Exhibition leads to still more being done in this direction. So far the Exhibition has been an immense success; half a million of people have already visited it, and thus the educational results are likely to be widespread.

Prof. Huxley, in opening the proceedings, said:—

It is doubtful whether any branch of industry can lay claim to greater antiquity than that of fishery. The origin would seem to be coeval with the earliest efforts of human ingenuity; for the oldest monuments of antiquity show us the fisherman in full possession of the implements of his calling; and even those tribes of savages who have reached neither the pastoral nor the agricultural stages of civilisation are skilled in the fabrication and in the use of the hook, the fish-spear, and the net. Nor is it easy to exaggerate the influence which the industry thus early practised and brought to a considerable degree of perfection has directly and indirectly exerted upon the destinies of mankind, and especially upon those of the nations of Europe. In our quarter of the globe, at any rate, fishery has been the foster-mother of navigation and commerce, the disseminator of the germs of civilisation. Having glanced at the development of the industries connected with fishing, more especially by the Phœnicians, he continued:—These few remarks must suffice to indicate the wide field of interesting research which fisheries offer to the philosophical historian, and I pass on to speak of the fisheries from the point of view of our present practical interests. The supply of food is, in the long run, the chief of these interests. Every nation has its anxiety on this score, but the question presses most heavily on those who, like ourselves, are constantly and rapidly adding to the population of a limited area, and who require more food than that area can possibly supply. Under these circumstances, it is satisfactory to reflect that the sea which shuts us in at the same time opens up to us supplies of food of almost unlimited extent. In reference to the relation which the fisheries bore to the total supply of food of those who had easy access to the sea, he quoted the following paragraph from the Report of the Fisheries Commissioners, 1866:—"The produce of the sea around our coasts bears a far higher proportion to that of the land than is generally imagined. The most frequented fishing-grounds are much more prolific of food than the same extent of the richest land. Once in a year an acre of good land, carefully tilled, produces a ton of corn or two or three hundredweight of meat or cheese. The same area at the bottom of the sea in the best fishing-grounds yields a greater weight of food to the persevering fisherman every week in the year. Five vessels belonging to the same source in a single night's fishing brought in seventeen tons' weight of fish, an amount of wholesome food equal in weight to that of fifty cattle or 300 sheep. The ground which these vessels covered during the night's fishing could not have exceeded an area of fifty acres." My colleagues and I made this statement a good many years ago. I have recently tried to discover what yield may be expected, not from the best natural fishing-grounds, but from piscicultural operations. At Comacchio, close to the embouchure of the Po in the Adriatic, there is a great shallow lagoon which covers some 70,000 acres, and in which pisciculture has been practised in a very ingenious manner for many centuries. The fish cultivated are eels, gray mullet, atherines, and soles; and, according to the figures given by M. Coste, the average yield for the sixteen years from 1798 to 1813 amounted to 5 cwt. per acre—that is to say, double the weight of cheese or meat which could have been obtained from the same area of good pasture land in the same time. Thus the seas around us are not only important sources of food, but they may be made still more important by the artificial development of their resources. But this Exhibition has brought another possibility within the range of practically interesting questions. A short time ago a visitor to the market might have seen fresh trout from New Zealand lying side by side with fresh salmon from Scandinavia and from the lakes and rivers of North America. Steam and refrigerating apparatus combined have made it possible for us to draw upon the whole world for our supplies of fresh fish. In my boyhood "Newcastle" was the furthest source of the

salmon cried about the streets of London, and that was generally pickled. My son, or at any rate my grandson, whenever he goes to buy fish, may be offered his choice between a fresh salmon from Ontario and another from Tasmania. The fishing industry being thus important and thus ancient, it is singular that it can hardly be said to have kept pace with the rapid improvement of almost every other branch of industrial occupation in modern times. If we contrast the progress of fishery with that of agriculture, for example, the comparison is not favourable to fishery. Within the last quarter of a century, or somewhat more, agriculture has been completely revolutionised, partly by scientific investigations into the conditions under which domestic animals and cultivated plants thrive, and partly by the application of mechanical contrivances and of steam as a motive power to agricultural processes. The same causes have produced such changes as have taken place in fishery, but progress has been much slower. It is now somewhat more than twenty years since I was first called upon to interest myself especially in the sea fisheries. And my astonishment was great when I discovered that the practical fisherman, as a rule, knew nothing whatever about fish, except the way to catch them. In answer to questions relating to the habits, the food, and the mode of propagation of fish —points, be it observed, of fundamental importance in any attempt to regulate fishing rationally—I usually met with vague and often absurd guesses in the place of positive knowledge. The Royal Commission, of which I was a member in 1864 and 1865, was issued chiefly on account of the allegation by the line fishermen that the trawlers destroy the spawn of the white fish—cod, haddock, whiting, and the like. But, in point of fact, the spawn which was produced in support of this allegation consisted of all sorts of soft marine organisms except fish. And if the men of practice had then known what the men of science have since discovered, that the eggs of cod, haddock, and plaice float at the top of the sea, they would have spared themselves and their fellow-fishermen, the trawlers, a great deal of unnecessary trouble and irritation. Thanks to the labours of Sars in the Scandinavian seas, of the German Fishery Commission in the Baltic and North Seas, and of the United States Fishery Commission in American waters, we now possess a great deal of accurate information about several of the most important of the food fishes, and the foundations of a scientific knowledge of the fisheries have been laid. But we are still very far behind scientific agriculture, and, as to the application of machinery and of steam to fishery operations, in this country at any rate, a commencement has been made, but hardly more. The relative backwardness of the fishing industry made a great impression on my colleagues and myself in the course of the inquiries of the Royal Commission to which I have referred; and I beg permission to quote some remarks on this subject which are to be found in our Report issued in 1866:—"When we consider the amount of care which has been bestowed on the improvement of agriculture, the national societies which are established for promoting it, and the scientific knowledge and engineering skill which have been enlisted in its aid, it seems strange that the sea fisheries have hitherto attracted so little of the public attention. There are few means of enterprise that present better chances of profit than our sea fisheries, and no object of greater utility could be named than the development of enterprise, skill, and mechanical ingenuity which might be elicited by the periodical exhibitions and publications of an influential society specially devoted to the British fisheries." Taking this Exhibition, the third of its kind, as evidence that the public attention to fisheries for which they hoped had been attained, he remarked that the conference opened that day formed an entirely new feature of such exhibitions, and expressed a hope that there was in them a germ of that which, by due process of evolution, might become a great society, having for its object the welfare and the development of the fisheries of these islands. He presently turned to the question whether fisheries are exhaustible; and, if so, whether anything can be done to prevent their exhaustion. He did not think it possible to give a categorical answer. There were fisheries and fisheries; but he had no doubt that there were some fisheries which were exhaustible. Instancing the salmon rivers, he said it was quite clear that those who would protect the fish must address themselves to man, who was reachable by force of law; and that it not only might be possible, but it was actually practicable, to so regulate the action of man with regard to a salmon river that no such process of extirpation should take place. But if we turned to the great sea fisheries, such as cod and herring fisheries, the case was entirely altered. Those who have watched these fisheries off the Lofoden Isles on the coast of Norway, say that the coming in of the cod in January and February is one of the most wonderful sights in the world; that the cod form what is called a "cod mountain," which may occupy a vertical height of from 20 to 30 fathoms—that is to say, 120 to 130 feet, in the sea; and that these shoals of enormous extent keep on coming in in great numbers from the westward and southward for a period of something like two months. The number of these fish is so prodigious that Prof. Sars, the most admirable authority, from whom I quote these details, tells us that when the fishermen let down their loaded lines, they feel the weight knocking against the bodies of the codfish for a long time before it gets to the bottom. I have made a computation, with the details of which I will not trouble you, which leads to this result, that if you allow the fish each of them four feet in length, and let them be a yard apart, there will be in a square mile of such shoals something like 120 million fish. I believe I am greatly understating the actual number, for I believe the fish lie much closer; but I would beg your attention to the bearing of this underestimate, because I do not know that the Lofoden fishery has ever yielded more than 30 million fish in a good season; and so far as I am aware the whole of the Norwegian fisheries, great as they are, do not yield more than 70 millions. So you will observe that one of these multitudinous shoals would be sufficient to supply all the fisheries of Norway completely, and to leave a large balance behind. And that is not all. These facts about the cod apply also to the herring; for not only Prof. Sars, but all observers who are familiar with the life of the cod when it has attained a considerable size, tell us that the main food of the cod is the herring, so that these 120 million of cod in the square mile have to be fed with herring, and it is easy to see, if you allow them only one herring a day, that the quantity of herring which they will want in the course of a week will be something like 840 million. Now I believe the whole Norwegian herring fishery has never reached the figure of 400 million fish—that is to say, one half the fish which this great shoal of codfish eats in a week would supply the whole of the Norwegian fisheries. On these and other grounds it seemed to him that this class of fisheries—cod, herring, pilchard, mackerel, &c.—might be regarded as inexhaustible. But he should not venture to say this of the whole of the sea fisheries—of the oyster fisheries, for example. Here, again, the operations of man become exceedingly important. Regarding the regulation as to close time for oysters as alone absolutely futile for the purpose of protection, he urged that the more logical provisions of government supervision in Denmark, France, and elsewhere, were impracticable of application beyond the three-mile limit of this country. It was under this conviction that the Commission to which he referred recommended the abolition of all restrictive measures. In conclusion, he pointed out how heavily this question bore on the social condition of the fisherman. Every act of legislation with regard to the fisherman created a new offence. If the common welfare and the common interest, said Prof. Huxley, can be clearly shown to render such regulations desirable or necessary, then of course fishermen must put up with this as they put up with anything else—as we all put up with such restrictions. But supposing that no good case is made out, supposing that regulations of this kind are made on insufficient inquiry and based on insufficient understanding of the circumstances of the case, then I am free to confess that I think those who make such laws deserve very much severer penalties than those who break them.

THE SCIENTIFIC WORK OF THE "VEGA"[1]

THE volume we have before us—the first of a series—contains the results of the scientific observations made during the cruise of the *Vega*, and to say this is obviously to indicate that it contains a rich supply of most valuable information as to that part of the Arctic Ocean which extends along the coasts of Siberia, which appears in the shape of a series of elaborate papers on different departments of natural history of the Arctic regions. Several parts of this volume are already known. Such are the "Reports to Dr. Oscar Dickson" written by Baron Nordenskjöld during the expedition, and read throughout the civilised

[1] "*Vega*-Expeditionens Vetenskapliga Iakttagelser, bearbetade af deltagare i resan och andra forskare, utgifna af A. E. Nordenskjöld." Vol. i. Part 1. (Stockholm, 1882.)

world as soon as they reached Europe; or his paper on the possibility of navigation in the Siberian Arctic Sea; or, again, his paper on auroræ (recently summarised in the pages of NATURE). The well-known "Reports" appear as they were written on board the *Vega*, but with a map "of the northern coast of the old continent, from Norway to Bering Strait," and with several maps of separate islands and bays. The other papers are quite new, and we find in this volume a medical report, by E. Almquist, on the health of the crew; a paper by A. Lindhagen, on the determinations of latitudes and longitudes, which will put an end to the discussions as to the accuracy of the changes made in the map of the northern coast of Siberia by the astronomers of the *Vega*; a paper by H. H. Hildebrandson (in French), on the meteorological work of the expedition, being a comparison of the climate of Pitlekaj (the *Vega's* wintering station) with the climate of other Arctic stations; several papers on the Chukches; an elaborate paper by A. Stuxberg, on the invertebrate fauna of the Siberian Arctic Sea; and a series of papers by F. R. Kjellman, A. N. Lundström, and E. Almquist, on the vegetation of the region visited.

It is known that the expedition of the *Vega* was—as is, however, always the case with so experienced a traveller as Nordenskjöld, and as it was with Parry—one of the most successful Arctic expeditions with regard to the health of the crew. No death was to be regretted, and all the thirty men of the crew reached Naples in the best condition. It is true that at Pitlekai the sun did not disappear for months under the horizon, and that the crew were not worn out by long sledge journeys. But still the climatic conditions were not at all favourable, on account of the variability of the weather and strong winds which blew with a twenty miles' speed even during frosts —30° strong. The precautions taken for maintaining a temperature as equal as possible in the cabins and for eliminating moisture, as well as for much exercise in the fresh air and the maintenance of cheerfulness among the crew, are not to be underrated. A daily distribution of lime-juice and of jam surely had also their importance as preservatives against scurvy, and this the more as the crew of the *Vega* had no opportunities of having supplies of fresh meat during the winter. The daily baking of fresh bread was a very good innovation; as to the preserved meat, the crew very soon had enough of it, and even salted meat was preferred to corned beef; only the finer and more expensive preserved soups and steaks were appreciated throughout the cruise.

The Chukches were of course the subject of anthropological and ethnographical studies, as far as possible. Mr. Nordquist publishes a most valuable Chukch dictionary, and Mr. Almquist communicates interesting observations on colour-blindness among the Chukches, two hundred men and a hundred women having been submitted to experiments in accordance with Prof. Holmgren's hints as to this kind of research with people whose language is unknown ("Om färgblindheten," &c., Upsala, 1877). The supposition of Helmholtz and Young as to the blindness of the lower races with regard to violet rays has not been confirmed as far as the Chukches are concerned; they certainly distinguish it, but they merely call it red. The same is true with regard to pale green and bright blue; they confound both, but the organs for green are not missing with them. Like other lower races, they use much red colour for their skins, yellow being comparatively rarely used for ornaments. It results also from M. Kjellman's paper on the culinary plants of the Chukches, that, contrary to Wrangel's assertion, they do not despise vegetable food. Their provisions of plants for the winter are as large as their provisions of meat and fat. This feature so much distinguishes them from all other inhabitants of the Arctic regions that one is inclined to admit that the time is not far removed from that when they cultivated some better situated plots of soil on the coast of the Arctic Ocean, or were compelled to leave lower latitudes which had a happier climate than that of the north-eastern extremity of Siberia. Their provisions in vegetables are a very strange mixture of various plants, among which the following are the most common:—*Cineraria palustris*, L., *Petasites frigida*, Fr., *Pedicularis sudetica* and *P. lanata*, Willd., *Rhodiola rosea*, L., *Claytonia acutifolia*, Willd., *Halianthus peploides*, Fr., *Polygonum polymorphum*, L., and *Salix boganidensis*, Trautvetter.

The most important papers in this volume are those devoted to the vegetation of the region visited, that is, to the lichens and mosses of the coast, to the algæ of the Siberian Sea, and to the phanerogamic flora of Novaya Zemlya, of the coast region, and of the Asiatic coast of Bering Strait. The lichens are comparatively rare on the coast; whole stretches are quite devoid of them, and the lichen flora is altogether poor as to the number of species. The Calicieæ are represented by but three species, and the whole group of the Sclerolichens only by five or six species, none of them being spread over the whole of the coast. The Stictaceæ are represented by a couple of species of *Nephroma*; the Pannariaceæ by five to six species; *Pyrenopsis* has but one species which is widely spread, but not very common. The character of the flora is nearly the same on the whole of the coast, but towards the south, where the country becomes inhabited, the flora undergoes a notable change. The Phanerogams become also comparatively rich towards the east, in the land of the Chukches, where the grasses appear in the shape of whole sods, without a mixture of moss. The Algæ are few in the Siberian Sea, the whole number of observed species being but twelve, that is, only one-half of the number of species that are known on the Murman coast and in the Sea of Spitzbergen. The characteristic feature of all Arctic Algæ being their large size, the Siberian Algæ seem to be an exception to this rule. The largest of them was a *Laminaria Aghardii*, 210 centimetres long and 37 cm. wide.

The papers by MM. Kjellman and Lundström on the Phanerogams of the explored region will be read with great interest both by the botanist and the geographer. They are not bare enumerations of plants, but elaborate sketches of botanical geography taking into account former botanical work in neighbouring tracts, and describing the flora in its dependence upon local conditions of climate and soil. The coast-flora of Northern Siberia is altogether poor, as it numbers but 150 species of Phanerogams; this number slightly increases, however, towards the east, where it reaches 221, as well as towards the west, 185 species being known from Novaya Zemlya. The Obi—at least as far as the coast region proper is concerned—is not a separation-line between the Arctic European and the Arctic Asiatic floras, as was expected by Hooker. Only the *Salix rotundifolia* and *Wahlbergella affinis* do not appear to the east of the great West Siberian river. Of the 150 species noticed, only one-third are Monocotyledons. This proportion increases, however, at certain places, and there are monocotyledonous species extending over large areas. However poor as to the number of species, the Siberian coast-flora still affords a variety of forms, as it has representatives of 33 different families and 93 different genera. The families which are the most represented in the coast-flora are those of Gramineæ and Cruciferæ, which number respectively 23 and 20 species. They are followed by those of the Compositæ, Saxifragaceæ, Ranunculaceæ, Cyperaceæ, and Caryophyllaceæ (15 to 11 species). The family of Saxifragaceæ is that which maintains the greatest number of species towards the north, eight species out of fourteen having been found even at Cape Chelyuskin; the Caryophyllaceæ nearly keep pace with the former; whilst the family which spreads least towards the north is that of Compositæ

which was represented only by two species at the mouth of the Taimyr and none at Cape Chelyuskin. So also with the Cyperaceæ and Ranunculaceæ. *Saxifraga oppositifolia* is not the most widely-spread species on the Siberian northern coast, as is the case for other parts of the Arctic region, other species of Saxifraga being as much or more extensively spread than it. The most usual phanerogamous plants on the coast seem to be the *Luzula arcuata*, var. *hyperborea*, and *Stellaria longipes*.

We shall not analyse the valuable paper by M. Kjellman on the flora of Novaya Zemlya, which is a summary of all that is known on this subject, and we shall notice but a few facts concerning the vegetation of the Siberian coast of Bering Strait. It is represented on M. Kjellman's lists by 221 species belonging to 41 families and 109 genera. The Compositæ, Cyperaceæ, Saxifragaceæ, Caryophyllaceæ, and Gramineæ, numbering from 20 to 15 species each, are here also the richest as to the number of species. But we find on the Asiatic coast of the Bering Strait a good many plants belonging to the American flora, as also to the flora of the Altai and Baikal regions, which are not met with elsewhere on the northern coast. No less than 53 species out of 221 appear only to the east of the Kolyma, which appears thus to be, for the coast-region, a more important boundary line than the Obi. This notable increase cannot be accounted for only by the milder character of this region, but it could be explained, in our opinion, if we took notice of the orography of Eastern Siberia, which favours, by the extension of its chains of mountains from south-west to north-east, the spread of both animals and plants in the same direction.

Dredging was very diligently carried on during the whole of the cruise of the *Vega* in the Arctic Ocean; and Mr. Stuxberg's map of dredgings made during the Swedish expeditions of 1875, 1876, and 1878 to 1879, is dotted with 33 spots in the Kara Sea, and with 90 spots along the Siberian coast to Bering Strait. The temperature of water obviously was found to be very low; even at a few fathoms below the surface it was from $-0{\cdot}9^{\circ}$ to $-2{\cdot}3^{\circ}$ at a depth of 50 metres, and it had a normal specific gravity of 1·027. The most uniformly spread animals in the Siberian coast-region of the Arctic Ocean, and in the Kara Sea, are undoubtedly the Crustaceans; the Echinoderms are comparatively few, as also are the Mollusca, Bryozoa, and Hydroids. The Crustaceans *Idothea Sabinei*, *Idothea entomon*, *Diastylis Rathkei*, *Atylus carinatus*, and *Acanthostephia Malmgreni*, are the most usual. The first, as known, has been found nearly everywhere in the Arctic Ocean; whilst the second proved to be specific for the whole of the Arctic coast of the old continent, for a stretch of nearly 160 degrees of longitude; it has been found also in the lakes of Sweden and Northern Russia, even in the Caspian and Lake Aral—Lake Baikal being till now the sole explored great lake of this part of the old continent where it has not yet been found. As to the vertical distribution of the animal forms, no distinct regions can be established. It must be observed, however, that the littoral region—about 30 fathoms deep—on account of its ice and sweet water brought by rivers, is nearly quite devoid of animals; even the littoral forms go to take refuge in the sublittoral region. Not only is the Siberian Sea very rich in forms of animals (the number of described Amphipods being as much as 59 out of 114 Amphipods known in all Arctic seas together); it contains also such a number of individuals of certain species, that Mr. Stuxberg describes about 20 real "formations" (*djurformationen*), each consisting of very large quantities of individuals of one given species, with a comparatively small mixture of other species. Such are the *Diastylis Rathkei*, *Reticulipora intricaria*, *Alcyonidium mammillatum*, *Chiridota lævis*, *Echinus dröbachiensis*, *Asterias Lincki*, *Archaster tenuisbinus*, *Ctenodiscus crispatus*, *Ophiacantha bidentata*, *Ophiocten sericeum*, *Ophioglypha nodosa*, *Astrophyton eucnemis*, *Antedon Eschrichti*, *Yoldia arctica*, and *Idothea entomon*, as also Ascidiæ, Actiniæ, and Hydroids. As a whole, the Siberian basin differs very much in its fauna from the other parts of the Arctic basin, and it has no less than 16 species that are characteristic of it. Novaya Zemlya is the limit of the fauna of the Siberian Sea, being a separation-line for many species.

The foregoing notice will give a general idea of the valuable material contained in the first volume of the "*Vega's* Scientific Work," and the manner it is treated. We have but to express the wish to see, as soon as possible, the appearance of the following volumes of this series. They will surely give a new and powerful impulse to the study of Northern Siberia. P. K.

NOTES

WE are glad to learn that Mr. Spottiswoode continues to go on favourably.

STILL another well-deserved honour for Sir Joseph Hooker. The Society of Arts' Albert Medal for "distinguished merit for promoting arts, manufactures, or commerce," has been awarded to him for the present year, for the eminent services which, as a botanist and scientific traveller, and as Director of the National Botanic Department, he has rendered to the arts, manufactures, and commerce by promoting an accurate knowledge of the flora and economic vegetable products of the several colonies and dependencies of the Empire.

AMONG those to whom the Council of the Society of Arts have awarded their silver medals are Mr. Alex. Siemens and Dr. Hopkinson, for their papers on "The Transmission of Power by Electricity," and "The Portrush Railway," and to Capt. Douglas Galton for his paper on "The Economy of Sanitation." Thanks were voted to Mr. W. H. Preece, F.R.S., for his paper on Electrical Exhibitions.

A SPECIAL extra meeting of the Anthropological Institute was held at the Piccadilly Hall on Tuesday, when the Botocudo Indians and a large ethnological collection from Brazil were exhibited by the kindness of Mr. C. Ribeiro, and Prof. A. H. Keane read a paper descriptive of the Botocudos.

MR. MARK H. JUDGE has resigned his position as Secretary and Curator of the Parkes Museum.

M. DE LESSEPS has declared officially at the Academy of Sciences the intention of the Suez Company to open a new canal. During the works the maritime way will be lighted by electricity, and an appeal has been addressed to physicists to present their several systems. The work will begin as soon as possible.

WE have received a favourable report of the National Museum, Bloemfontein, Orange Free State. Considerable collections are being brought together, but the committee should not forget that the chief object of such a museum ought to be to make its collections mainly representative of the interesting country in which it is placed.

DR. KERR of Canton is publishing in Chinese a complete work on the theory and practice of medicine, compiled from European standard works upon that subject. The sections on fevers, and diseases of the stomach, have already been published, while those on affections of the heart and lungs have just been issued. Volumes on the kidneys and nervous system are in the press. The translator has omitted the discussion of all unsettled theories and disputed points. The volumes are printed from wooden blocks, clearly and evenly cut, and are sold at a price which brings them within the reach of all.

Mr. J. W. Taylor of Leeds, who is the editor of the *Journal of Conchology*, has issued a prospectus for a "Monograph of the Land and Freshwater Mollusca of the British Fauna," and he invites the assistance of conchologists towards his propo ed undertaking. According to the prospectus the work will be very comprehensive, and will include the subjects of variation, geographical and local distribution, synonomy and bibliography, "biological aspect and relation to environment." It would be desirable to add distribution in point of time or the palæontological aspect. Mr. Taylor has given specimens of the work in some of the lately published numbers of his *Journal of Conchology*, and they seem to be carefully and almost exhaustively done. We hope the cost of this work will place it within the means of the numerous and comparatively poor conchologists in the north of England, as so many manuals on the subject have already been published at very moderate prices. Great service would likewise be done to natural history by reducing the excessive number of so called species fabricated during the last twenty years by some Continental conchologists. The judicious remark made by Hooker and Thomson in the introduction to their "Flora Indica" ought always to be borne in mind, viz. that "the discovery of a form uniting two others previously thought distinct, is much more important than that of a totally new species, inasmuch as the correction of an error is a greater boon to science than a step in advance."

The *Union Médicale* of June 2 announces a discovery of the highest scientific interest, and which, if it turns out to be real, will show that prehistoric man is no longer a myth. On piercing a new gallery in a coal-mine at Bully-Grenay (Pas-de-Calais), a cavern was broken into containing six fossil human bodies intact—a man, two women, and three children—as well as the remains of arms and utensils in petrified wood and stone, and numerous fragments of mammals and fish. A second subterranean cave contained eleven bodies of large dimensions, several animals, and a great number of various objects, together with precious stones. The walls were decorated with designs of combats between men and animals of gigantic size. A third and still larger chamber appeared to be empty, but could not be entered in consequence of the carbonic acid it contained, which is being removed by ventilators. The fossil bodies have been brought up to the surface, and five of them will be exhibited at the *mairie* of Lens; the others are to be sent to Lille in order to undergo examination by the Faculté des Sciences. Representatives of the Académie des Sciences of Paris and of the British Museum having been telegraphed for, are expected to be present.

The Lords of the Committee of Council on Education have sanctioned the addition of hygiene to the list of sciences in which grants are made by the Department. A syllabus has been prepared, and will shortly be issued to science schools and clas es.

From the third Annual Report of the Hampstead Naturalists' Club we are glad to see that the society is in a prosperous condition, and is gradually getting together a useful museum.

G. P. Putnam's Sons of New York have published a nicely got up and profusely illustrated Guide to the Yellowstone National Park, by Mr. H. J. Winser, which those proceeding to the States for their holiday would do well to get.

Next month Messrs. Williams and Norgate will publish a new work, entitled "The Natural Genesis," in two volumes, by Mr. Gerald Massey, containing the Natural Genesis and Typology of Primitive Customs; Gesture-signs, Ideographs, and Primordial Onomatopœia; Time and Numbers; the Serpent, Dragon, and other Elementaries; the Tree, Cross, and Four Corners; the Great Mother, Twins, Triads, and Trinity; the Mythical Creations; the Fall in Heaven and on Earth; the Deluges and Ark; and Equinoctial Christology.

A writer in a recent number of the *North China Herald*, referring to fossils in China, remarks that the Chinese have never advanced a theory to explain their existence. In their books references are made to fossil shells, crabs, fish, trees, &c., but no attempt is made to account for their occurrence in solid rock. The little that is said is mostly of the marvellous sort. Ammonites are petrified snakes; fossil brachiopods (lamp-shells) are called "stone swallows," and are said to come to life and fly from their hiding places at the approach of wind and rain, changing again to stones on the return of fair weather. Fossil fish appear and disappear at pleasure, and their appearance prognosticates a plentiful harvest and prosperous times. One author supposes that the figures of birds, beasts, and plants, which he had seen on certain slabs, must be the work of gods or devils, for no human hand could chisel anything so minute and delicate.

Crackers play a large part in the superstitious observances of the ordinary Chinese. It is a popular belief that the evil spirits everywhere inhabiting the air are dispersed by crackling noises, attended by fire and smoke. Accordingly crackers are used on all special occasions to frighten away the demons who are tormenting a sick person, or who crowd around the people at the beginning of the New Year. Bamboo, which when burning emits a crackling sound, is also used for the same purpose.

We have received the Report of the West Kent Natural History, Microscopical, and Photographic Society for 1882-83. It appears to be more bulky than its predecessors, extending to 68 pp. 8vo. The President (Dr. F. T. Taylor) discourses on Bacteria and Vivisection; Mr. J. Glaisher, F.R.S., gives a very instructive paper on the extraordinary meteorological conditions between October 1881 and May 1882, illustrated by two diagrams indicating the mean daily barometric and thermometric readings, and their departure from the mean, as observed at Blackheath; Mr. J. Jenner Weir, F.L.S., discusses on the types of variation in Lepidoptera, in which is embodied much useful information; Mr. Stone alludes to certain points in the economy of wasps; Mr. Heisch's notes on "Adulteration" are of practical interest. In their next Report this old-established Society may perhaps think it advisable to give a tabular indication of the "contents"; the same remark would apply equally to the publications of other local societies.

Under the title of "Lantern Readings" Mr. Lant Carpenter has issued a pamphlet to be used (when necessary) with the first series of the biological lantern slides which we referred to in a recent number. These slides are now ready, and may be obtained from York and Son. The pamphlet and slides are intended to illustrate the results of the voyage of the *Challenger*. There are descriptions of forty-two slides in all, and "preliminary hints" show how the pamphlet is to be used.

The additions to the Zoological Society's Gardens during the past week include two Malbrouck Monkeys (*Cercopithecus cynosurus* ♂ ♀) from West Africa, presented respectively by Mr. L. Morris and Mr. A. M. Moore; a Macaque Monkey (*Macacus cynomolgus* ♀) from India, presented by Mrs. E. J. H. Sprague; a Rhesus Monkey (*Macacus erythræus* ♂) from India, presented by Mr. C. T. Pollock; a Bonnet Monkey (*Macacus radiatus* ♀) from India, presented by Mr. F. Nelson; two Mauge's Dasyures (*Dasyurus maugæi*) from Australia, presented by Sir Louis S. Jackson, F.Z.S.; two Earl's Weka Rails (*Ocydromus earlii*) from North Island, New Zealand, a Black-backed Porphyrio (*Porphyrio melanotis*) from Australia, presented by Capt. R. Todd; three Common Kingfishers (*Alcedo ispida*), British, presented by the Hon. and Rev. F. G. Dutton; a Common Night Heron (*Nycticorax griseus*), European, presented by Mr. H. H. Blacklock; a King Penguin (*Aptenodytes pennanti*), two Upland

Geese (*Bernicla magellanica* ♂ ♀), two Ruddy-headed Geese (*Bernicla rubidiceps*) from the Falkland Islands, presented by Mr. R. C. Packe; three Common Pheasants (*Phasianus colchicus* ♂ ♀ ♀), British, presented by Mr. H. T. Bowes; an Indian Python (*Python molurus*) from India, presented by Mr. G. E. Shute; a Sykes's Monkey (*Cercopithecus albigularis*), a Philantomba Antelope (*Cephalophus maxwelli* ♀), an Elate Hornbill (*Buceros elatus*), a Jardine's Parrot (*Pæocephalus gulielmi*) from West Africa, an Indian Civet (*Viverricula indica*), two Wandering Tree Pies (*Dendrocitta vagabunda*), from India, a Red-sided Eclectus (*Eclectus polychlorus*) from New Guinea, five Red-bellied Conures (*Conurus vittatus*), a Giant Toad (*Bufo agua*) from Brazil, a Horned Lizard (*Phrynosoma cornutum*) from Texas, four Cornish Choughs (*Fregilus graculus*), British, purchased; a Common Rhea (*Rhea americana*) from South America, received in exchange; two Indian Pythons (*Python molurus*) from India, received on approval; a Japanese Deer (*Cervus sika* ♂), born in the Gardens.

OUR ASTRONOMICAL COLUMN

The Paris General Catalogue of Stars.—In the last Annual Report issued by Admiral Mouchez we find particulars of the progress of formation of this extensive and important catalogue. It is intended to contain all the stars observed at Paris during the forty-five years 1837 to 1881 inclusive, about 40,000, but it is mainly the result of the revision of Lalande's stars in the *Histoire Céleste*; indeed, for several years past, the meridian instruments have been almost wholly occupied upon this work, and upwards of 27,000 observations were made during 1882, the year to which the Report refers. The entire number of observations upon which the Paris General Catalogue will be founded is about 350,000. The positions are referred to three principal epochs; 1845·0 for the years 1837-53, 1860·0 for the years 1854-67, and 1875·0 for the years 1868-82. A specimen of the form in which it is intended to print the catalogue is appended to the Report. The right ascensions and declinations are given for each principal epoch, with the number and mean year of the observations. The precessions are reckoned from the year 1875, with the term depending upon the square of the time. The magnitudes and the differences from the positions of the *Histoire Céleste* are annexed, and where a star has not been observed by Lalande a synonym in some other catalogue is given. In the first column we have the ordinal number, and in the second the star's number in the reduced catalogue of the *Histoire Céleste*. It is mentioned in the Report that M. Bossert had undertaken a new determination of the places of the stars in that work, making use of the reduction-tables of the late Doctor von Asten, which are more exact than the tables of Hansen and Nissen, employed for the catalogue published in 1847. M. Bossert has already effected the reduction of 2,300 stars, a voluntary labour which has occupied his leisure hours. It would add to the value of the columns showing the differences between the new Paris positions and those of Lalande, if the comparisons could be made with places resulting from the application of von Asten's tables, though it might be necessary to supplement M. Bossert's laudable efforts. In the last Greenwich Catalogue (1872) the precessions are given to four places of decimals in right ascension (time), and to three places in north polar distance; the Paris Catalogue gives these quantities with a figure less, which we are inclined to regard as a retrograde step.

This General Catalogue of the Observatory of Paris is to comprise two parts, which will be published simultaneously; the first part forming the catalogue proper, and the second containing details of the observations upon which the mean positions are founded. Each part will be composed of four volumes; the first volume of each is intended to appear during the year 1884.

Encke's Comet in the Years 1871–1881.—At the sitting of the Paris Academy of Sciences on June 11, M. Tisserand communicated a note by Dr. Backlund, of the Observatory of Pulkowa, relative to the motion of Encke's Comet in the interval 1871–1881. To complete the theory of this comet, it has been necessary to introduce an empirical to the mean motion of the form $\mu'\left(\frac{t}{1200}\right)$. The quantity μ', which was found to be nearly constant during the period 1819–1868, appears to have undergone a considerable variation about the latter epoch. Dr. Backlund bases his calculations upon osculating elements for October 27, 1874, which he considered exact enough for his purpose: they give—

$$\mu = 1079''\cdot33355 + \mu'\tau \left(\text{where } \tau = \frac{t}{1200}\right)$$
$$\mu' = + 0\cdot051731$$

After having carefully reviewed the computation of perturbations by Asten, and calculated by two different methods the perturbations during the revolution 1878–1881, Dr. Backlund compared the elements with the observations made in the years 1871, 1875, 1878, and 1881. By means of this comparison, he obtains corrections to the elements, and, observing that if there exists a tangential force, which varies the dimensions of the comet's orbit, its effect is not only secular, but also periodic, the periodic terms being always very small, except in the expression for the mean anomaly. This he takes into account, and finally deduces for the corrections of the two quantities above—

$$\Delta\mu = + 0''\cdot004745$$
$$\Delta\mu' = - 0\cdot0059867$$

Hence, he says, his investigation proves that the acceleration of the mean motion in the period 1871–1881 was less than half the value found by Encke and Asten for the period 1819–1865. Aten's value is + 0·104418.

CHEMICAL NOTES

Interesting experiments on the luminosity of gases are described by W. Siemens in *Ann. Phys. Chim.* [(ii.) 18, 311], and by E. Wiedemann [*ib.* 509]. Gases free from solid particles do not become luminous at high temperatures, nor is the luminosity of a flame due to incandescence of the products of combustion; if the gases are strongly heated before being burnt, the flame becomes hotter and shorter than it is when the preliminary heating is omitted, and the luminous flame is seen to be distinctly separated from the non-luminous products of combustion. Siemens seems inclined to regard the chemical action which proceeds as the cause of luminosity: if the existence of an envelope of ether around the molecules is assumed, then the reaction of one molecule on another may be regarded as starting vibrations in this envelope, which vibrations give rise to heat and light rays. Wiedemann especially considers the luminosity of gases under the influence of electric discharges: he thinks that in the process of charging the electrodes the ethereal envelopes of some of the gas molecules are distorted; when discharge occurs these envelopes are set into motion, and hence the luminous effects.

Some time ago Ostwald deduced the relative affinities of various acids in terms of nitric acid taken as 100; by relative affinity is meant the proportion in which two acids divide themselves between one base, all the reacting substances being in solution. Ostwald has recently investigated this subject by a method different from that formerly employed; he has studied the rates of action of various acids on acetamide, and from the results he has deduced the relative velocities of action, and hence the relative affinities. The following table contains the results. In column II. are placed figures representing the results of his former experiments—

		I.	II.
Hydrochloric	acid	100	98·0
Nitric	,,	98	100
Hydrobromic	,,	98	95
Trichloracetic	,,	80	80
Dichloracetic	,,	40·8	33
Monochloracetic	,,	13·0	7
Formic	,,	5·2	3·9
Lactic	,,	5·2	3·3
Acetic	,,	2·3	1·2
Sulphuric	,,	65·4	66·7
Oxalic	,,	22·6	—
Tartaric	,,	7·5	5·2
Malic	,,	4·7	2·9
Succinic	,,	2·5	1·5
Citric	,,	4·0	—
Phosphoric	,,	3·6	—
Arsenic	,,	3·5	—

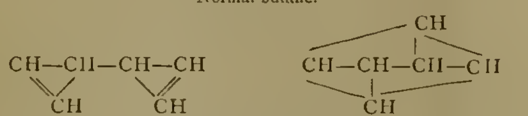
M. Spring continues his researches into the influence of great pressure upon chemical reactions: at a pressure of about

6500 atmospheres he finds that sulphur combines with magnesium, zinc, iron, cadmium, bismuth, lead, copper, silver, tin, and antimony. Sulphur and phosphorus do not combine when compressed together (*Berichte*, xvi. 999).

BENZENE is perhaps the most important body in the whole range of chemistry, not on account of any intrinsic interest in the substance itself, but because of the immense number of its derivatives. The constitution of these derivatives must depend upon the structure of the benzene molecule itself, and this problem is therefore one of the most interesting that presents itself to the chemist. Any idea that can throw light upon this subject is worthy of attention, and the more so as long as the least doubt exists as to whether benzene can yield more than three di, tri, or tetra derivatives, or more than one mono or penta derivative, the substituting groups being the same. Again, it is possible that benzene may exist in two or more isomeric modifications (disregarding dipropargyl), and the difference found by V. Meyer (*Ber.* xv. 2893) between two samples of benzene, both presumably pure, would seem to point in this direction. The mere fact, therefore, that one formula is good and useful is no condemnation of any other formula that may be proposed. M. Mendeléeff has suggested that benzene may be regarded as a normal butane, in which six hydrogen atoms are replaced by two triad groups, CH. If we allow that benzene is best represented as containing six CH groups, and there seems as yet no reason for departing from this supposition, then this replacement may take place in two ways, as shown by the following formulæ:—

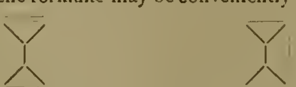
$$CH_3—CH_2—CH_2—CH_3$$

Normal butane.



Benzenes derived therefrom.

These two benzene formulæ may be conveniently written thus:—



and these expressions show at a glance the difference between them. The second is identical with Ladenburg's prism formula, the advantages of which do not need recounting. The first, so far as double and single linkings are concerned, is intermediate between the prism formula and Kekulé's. It lends itself in a particularly ready way to the expression of more complex formulæ, as of naphthaline, &c., but does not show the hexad nature of the benzene molecule. Moreover, it shows possible two mono or penta derivatives, and five each di, tri, and tetra derivatives, a capability that is not yet needed; and a formula should be a concise expression of facts, and should as far as possible show the limits of those facts. Thus, however valuable the suggestion of M. Mendeléeff may be as showing a possible method of synthesising benzene, it does not appear to be practically useful as indicating its constitution, though the future chemistry of benzene may require such a formula as the one referred to above.

PROF. MENDELÉEFF, to avoid the superheating which takes place during ordinary fractional distillation with a dephlegmator tube, has devised a modified method for the oils from Baku petroleums boiling between 15° and 150°, which consists in passing the vapours from the distilling flask by means of the dephlegmator, or delivery tube, to the bottom of a second similar flask, and from this to a third, and so on; the heated vapours from the one providing the necessary heat for the distillation of the next, &c. In this manner a great number of fractions at intervals of two degrees were obtained. By comparing boiling points and specific gravities of products the author concludes that Baku oils contain similar hydrocarbons to American petroleum, and in addition a hydrocarbon boiling at 55° and same specific gravity as hexan with the properties of an unsaturated compound. The great bulk of the Caspian petroleums appears to consist, in addition to derivatives of marsh gas, of C_nH_{2n} hydrocarbons, and also some members of the C_nH_n or acetylene series.

SOME interesting results have been obtained by Spring (*Ber. Ber.*) by washing precipitated sulphide of copper for several weeks until all traces of salts were removed. It was then found that the sulphide dissolved to a black liquid, with slight green fluorescence, in water. The solution might be boiled and evaporated without change; slight traces of salts caused precipitation. The author has also obtained sulphide of tin and oxides of antimony and manganese in a condition perfectly soluble in water. Sulphide of tin on evaporation of its solution in vacuo forms a transparent red glass.

GEOGRAPHICAL NOTES

ON June 6 Baron Nordenskjöld's Greenland expedition arrived at Reykjavik in the steamer *Sophia*. The *Sophia* lay at Reykjavik for a few days, and in the meantime Baron Nordenskjöld and the geologists of the party examined the coal deposits which occur in Bergarfiord. Dr. Arpi, a Swedish philologist, who has resided some time in Iceland and acquired a thorough knowledge of the language, accompanied the expedition thither, and will, along with two other men of science, remain in Iceland after the *Sophia* has left.

WE learn from *Science* that a party for the relief of the observers under Lieut. Greely at Lady Franklin Bay was to leave St. John's, Newfoundland, on one of the steam sealing-vessels belonging to that port, about June 15, probably accompanied by a naval vessel as tender. It will be commanded by Lieut. E. A. Garlington, U.S.A., and composed of twelve men, of whom ten are stated to be old sailors and accustomed to the use of boats. Twenty dogs, native drivers, and a supply of fur clothing, have been secured at Godhavn, Greenland. The party at Lady Franklin Bay will be reached and withdrawn if the state of the ice permits. If not, the relief party is to be landed on Littleton Island, and while part of them are engaged in preparing winter quarters, Lieut. Garlington will endeavour to open communication by sledges with Greely's people. In the failure of the first attempt, another will be made in the spring of 1884. It is to be hoped, if Greely is not reached, that an attempt will be made to leave at Cape Hawkes or Cape Sabine, if not the relief party as a whole, which would be best, at least a boat by which the open water to be anticipated between those points and Littleton Island next year (1884) may be passed by a retreating party, which might well find their own boat unseaworthy after dragging it over many miles of hummocky ice, if, indeed, they did not find themselves obliged to abandon it. Further, the schooner *Leo* is on the point of sailing for Point Barrow to withdraw the signal service observing party under Lieut. Ray, in compliance with the act passed by the last Congress. To utilise the opportunity, Mr. Marr, of the U.S. Coast-Survey, will accompany the vessel with the design of making absolute magnetic determinations, of fixing the astronomical position of the station, and of making pendulum observations.

IN a communication from the Russian Geographical Society we are informed that Col. Prejevalsky is about to start on his fourth journey to Central Asia, accompanied by two officers and seventeen men. The Emperor has granted to the Society 43,000 roubles for the purpose of Col. Prejevalsky's journey. The Society is also sending out a new expedition under M. Potanin, who is now completing the publication of the two last volumes on his journey of 1879–80. He will start in July for South-East Mongolia and the adjacent parts of China; he will be accompanied by a naturalist and M. Skassi, the companion of Severtzov in his exploration of the Pamir. The funds are being supplied partly by the Society and partly by M. Sookachef, a Siberian merchant.

IN the same communication we are informed that the average temperature of January and February at the Russian Polar station at Sagastyr, on the mouth of the Lena, was about −50° C. Thanks to the Governor-General of Eastern Siberia there has been organised a special postal service between Jakutsk and Sagastyr once a month. The observing party will most probably remain at the station up to the end of October, *i.e.* until the river is frozen.

THE last number of the *Zeitschrift der Gesellschaft fur Erdkunde zu Berlin* (Bd. 18, Heft 2) contains a paper by Herr van Langegg, entitled "Nara eine alte Kaiserstadt," describing the town of Nara, not far from Kioto, in Japan, at one time the capital of the country, and still much renowned for its temples. The celebrated colossal statue of Buddha there is fully described. The following figures give some notion of its dimensions:—Its weight is 500,000 kilog.; 3,000,000 kilog. of wood were con-

sumed in making the bronze, which consists of 250 kilog. of gold, 8413·5 of tin, 977 of mercury, and 493 of copper. The present image only dates from 1801.

We have received a German pamphlet by Herr Max Buch, on "Finland and its Nationality Question," being a reprint of papers which have appeared in recent issues of the *Ausland*. In the limited space of seventy-four pages the author gives a short but correct description of Finland, of the prehistoric Finns, according to Ahlquist's researches, of the history of the country, and of the present state of the "national question." He summarises the excellent researches by Retzius on the race-characters of the Finns—as far as can be done in a few pages—and dwells upon the recent efforts of Finnish writers towards the development of the Finnish language and literature as a reaction against the former supremacy of the Swedish language and influence. We notice the interesting fact that although only 7·5 per cent. of the Finns can now read and write, and 70 per cent. read, primary instruction has taken during the last few years a great extension. The number of State schools being too limited, they are supplemented by private instruction. Thus, of the 342,836 children from seven to sixteen years old of the Lutheran Finnish population, only 6983 had not received primary instruction in 1877 (1801 of them on account of disease). But only 26,900 went to the State schools, whilst 116,201 children received primary instruction in private ambulatory schools, and 177,925 at home.

The last number of the *Izvestia* of the Russian Geographical Society contains several interesting papers. M. Veselago gives a sketch of the life and work of the late Count Lütke. Prof. Fr. Schmidt discusses again the claim of Wrangel to the discovery of the land situated north of the Cape Yakan. He tries to prove, against Nordenskjöld, that Wrangel was right in denying the existence of a land which Andréeff said he saw from the fifth island of the Medvyejiy Archipelago; but he did not deny the existence of a land situated north of Cape Yakan. Prof. Schmidt admits, however, that even with regard to this land, Wrangel wrote "in different parts of his report with a varying degree of certainty as to the probability of its existence." M. Karzin, an official of the Verkhoyansk district, having been struck with the terrible fate of De Long, publishes a most valuable list of all settlements and places where human beings can be met with at different seasons on the coast of North-Eastern Siberia. M. Andréeff publishes a brief account of his hydrographical researches in the White Sea and on the Murman coast during the last three years. The flora of the coast becomes very poor north of Archangel. At the Svyatoy Noss lighthouse it consists only of lichens, mosses, and creeping brushes of *Betula nana*. It improves, however, west of Kildin and especially west of the Ribachiy peninsula, offering excellent forests and meadows at the new colony at Pechenga. The yearly average temperature, which is but $-0°·6$ Celsius at Archangel, and $-2°·4$ at the Svyatoy Noss lighthouse, reaches $-1°·1$ at Kola, and $+1°·4$ at Vardö. This increase of temperature is due, as is known, to the warm current which flows along the coast. Thus, at Svyatoy Noss, during the hottest days, the temperature of water does not exceed 6°·9; and during the autumn it reaches but 1°·9. To the west of 30° 6′ it suddenly becomes double that. In the spring the warm streamlets reach 4°·3, whilst the cold ones, flowing close by, reach but 1°·9; and during the summer the warm streamlets reach 12°·5, whilst the cold ones, close by, reach 6°·9 to 7°·5. It appears thus that one isolated measurement of temperature of water is of little value, the warm current being not so compact along the Murman coast as elsewhere. Under 33° 6′ E. long. it leaves the coast and flows towards the north-north-east. The positions taken by the warm current at the Murman coast vary with the seasons, and depend upon the prevailing winds. From April to August it touches the coast, but later on it is driven north by the southern winds; in October it already flows off Vardö. Its position varies also for different years, depending upon the prevailing winds. The richness of the fishing depends entirely upon the position taken by the warm current. In 1881, the Norwegians, owing to the current flowing in their waters, had the richest prey, whilst in 1882, the richest prey for a twenty years' series was given by the warm current to the Russian fishers. The same number of the *Izvestia* contains the first sheets of M. Polakoff's reports on his researches in Sakhalin, and M. Mezhoff's bibliographical index of the Russian geographical literature for the year 1880.

M. Thouar, the French traveller, has written a letter from Chili, in which he says that several members of the exploring party under Dr. Jules Crevaux, who was massacred with most of his followers in the early part of last year by Indians while making explorations along the Bolivian part of the Pilcomayo, are believed to be still alive, but prisoners in the hands of the Indians.

THE CAUSE OF EVIDENT MAGNETISM IN IRON, STEEL, AND OTHER MAGNETIC METALS [1]

Neutrality

The apparatus needed for researches upon evident external polarity requires no very great skill or thought, but simply an apparatus to measure correctly the force of the evident repulsion or attraction; in the case of neutrality, however, the external polarity disappears, and we consequently require special apparatus, together with the utmost care and reflection in its use.

From numerous researches previously made by means of the induction balance, the results of which I have already published, I felt convinced that in investigating the cause of magnetism and neutrality I should have in it the aid of the most powerful instrument of research ever brought to bear upon the molecular construction of iron, as indeed of all metals. It neglects all forces which do not produce a change in the molecular structure, and enables us to penetrate at once to the interior of a magnet or piece of iron, observing only its peculiar structure and the change which takes place during magnetisation or apparent neutrality.

The induction balance is affected by three distinct arrangements of molecular structure in iron and steel, by means of which we have apparent external neutrality.

Fig. 1 shows several polar directions of the molecules as indicated by the arrows. Poisson assumed, as a necessity of his theory, that a molecule is spherical, but Dr. Joule's experimental proof of the elongation of iron by 1/720,000th of its length when magnetised, proves at least that its form is not spherical; and as I am unable at present to demonstrate my own views as to its exact form, I have simply indicated its polar direction by arrows—the dotted oval lines merely indicating its limits of free elastic rotation.

In Fig. 1, at A, we have neutrality by the mutual attraction of each pair of molecules, being the shortest path in which they could satisfy their mutual attractions. At B we have the case of superposed magnetism of equal external value, rendering the wire or rod apparently neutral, although a lower series of molecules are rotated in the opposite direction to the upper series, giving to the rod opposite and equal polarities. At C we have the molecules arranged in a circular chain around the axis of a wire or rod through which an electric current has passed. At D we have the evident polarity induced by the earth's directive influence when a soft iron rod is held in the magnetic meridian. At E we have a longitudinal neutrality produced in the same rod when placed magnetic west, the polarity in the latter case being transversal.

In all these cases we have a perfectly symmetrical arrangement, and I have not yet found a single case in well-annealed soft iron in which I could detect a heterogeneous arrangement, as supposed by Ampère, De la Rive, Weber, Wiedermann, and Maxwell.

We can only study neutrality with perfectly soft Swedish iron. Hard iron and steel retain previous magnetisations, and an apparent external neutrality would in most cases be the superposition of one magnetism upon another of equal external force in the opposite direction, as shown in B, Fig. 1. Perfectly soft iron we can easily free, by vibrations, from the slightest trace of previous magnetism, and study the neutrality produced under varying conditions.

If we take a flat bar of soft iron, of 30 or more centimetres in length, and hold it vertically (giving while thus held a few torsions, vibrations, or, better still, a few slight blows with a wooden mallet, in order to allow its molecules to rotate with perfect freedom), we find its lower end to be of strong north polarity, and its upper end south. On reversing the rod and repeating the vibrations, we find that its lower end has pre-

[1] Paper read before the Society of Telegraph Engineers and of Electricians, on May 24, 1883, by Prof. D. E. Hughes, F.R.S., Vice-President Continued from p. 162.

cisely a similar north polarity. Thus the iron is homogeneous, and its polarity symmetrical. If we now magnetise this rod to produce a strong south pole at its lower portion, we can gradually reverse this polarity, by the influence of earth's magnetism, by slightly tapping the upper extremity with a small wooden mallet. If we observe this rod by means of a direction needle at all parts, and successively during its gradual passage from one polarity to the other, there will be no sudden break into a haphazard arrangement, but a gradual and perfectly symmetrical rotation from one direction to that of the opposite polarity.

If this rod is placed east and west, having first, say, a north polarity to the right, we can gradually discharge or rotate the molecules to zero, and as gradually reverse the polarity by simply inclining the rod so as to be slightly influenced by earth's magnetism; and at no portion of this passage from one polarity to neutrality, and to that of the opposite name, will there be found a break of continuity of rotation or haphazard arrangement. If we rotate this rod slowly, horizontally or vertically, taking observations at each few degrees of rotation of an entire revolution, we find still the same gradual symmetrical change of polarity, and that its symmetry is as complete at neutrality as in evident polarity.

In all these cases there is no complete neutrality, the longitudinal polarity simply becoming transversal when the rod is east and west. F, G, H, I, J, Fig. 1, show this gradual change, H being neutral longitudinally, but polarised transversely. If, in place of the rod, we take a small square soft iron plate and allow its molecules freedom under the sole influence of the earth's magnetism, then we invariably find the polarity in the direction of the magnetic dip, no matter in what position it be held, and a sphere of soft iron could only be polarised in a similar direction. Thus we can never obtain complete external neutrality whilst the molecules have freedom and do not form an internal closed circle of mutual attractions; and whatever theory we may adopt as to the cause of polarity in the molecule, such as Coulomb's, Poisson's, Ampère's, or Weber's, there can exist no haphazard arrangement in perfectly soft iron, as long as it is free from all external causes except the influence of the earth; consequently these theories are wrong in one of their most essential parts.

We can, however, produce a closed circle of mutual attraction in iron and steel, producing complete neutrality as long as the structure is not destroyed by some stronger external directing influence.

Oersted discovered that an external magnetic needle places itself perpendicular to an electric current; and we should expect that, if the molecules of an iron wire possessed inherent polarity and could rotate, a similar effect would take place in the interior of the wire to that observed by Oersted. Wiedermann first remarked this effect, and it has been known as circular magnetism. This circle, however, consists really in each molecule having placed itself perpendicular to the current, simply obeying Oersted's law, and thus forming a complete circle in which the mutual attractions of the molecules forming that circle are satisfied, as shown at C, Fig. 1. This wire becomes completely neutral, any previous symmetrical arrangement of polarity rotating to form its complete circle of attractions; and we can thus form in hard iron and steel a neutrality extremely difficult to break up or destroy. We have evident proof that this

neutrality consists of a closed chain, or circle, as by torsion we can partially deflect them on either side; thus, from a perfect externally neutral wire, producing either polarity, by simple mechanical angular displacement of the molecules, as by right- or left-handed torsion.

If we magnetise a wire placed east and west, it will retain this polarity until freed by vibrations, as already remarked. If we pass an electric current through this magnetised wire, we can notice the gradual rotation of the molecules, and the formation of the circular neutrality. If we commence with a weak current, gradually increasing its strength, we can rotate them as slowly as may be desired. There is no sudden break or haphazard moment of neutrality: the movements to perfect zero are accomplished with perfect symmetry throughout.

We can produce a more perfect and shorter circle of attractions by the superposition of magnetism, as at B, Fig. 1. If we magnetise a piece of steel or iron in a given direction with a strong magnetic directing power, the magnetism penetrates to a certain depth. If we slightly diminish the magnetising power, and magnetise the rod in a contrary direction, we may reduce it to zero by the superposition of an exterior magnetism upon one of a contrary name existing at a greater depth; and if we continue this operation, gradually diminishing the force at each reversal, we can easily superpose ten or more distinct symmetrical arrangements, and as their mutual attractions are satisfied in a shorter circle than that produced by electricity, it is extremely difficult to destroy this formation when once produced.

The induction balance affords also some reasons for believing that the molecules not only form a closed circle of attractions, as at B, but that they can mutually react upon each other, so as to close a circle of attractions as a double molecule, as shown at A. The experimental evidence, however, is not sufficient to dwell on this point, as the neutrality obtained by superposition is somewhat similar in its external effects.

We can produce a perfectly symmetrical closed circle of attractions of the nature of the neutrality of C, Fig. 1, by forming a steel wire into a closed circle, 10 centimetres in diameter, if this wire is well joined at its extremities by twisting and soldering. We can then magnetise this ring by slowly revolving it at the extremity of one pole of a strong permanent magnet; and, to avoid consequent poles at the part last touching the magnet, we should have a graduating wedge of wood, so that whilst revolving, it may be gradually removed to greater distance. This wire will then contain no consequent points or external magnetism: it will be found perfectly neutral in all parts of its closed circle. Its neutrality is similar to C, Fig. 1; for if we cut this wire at any point we find extremely strong magnetic polarity, being magnetised by this method to saturation, and having retained (which it will indefinitely) its circle of attractions complete.

I have already shown that soft iron, when its molecules are allowed perfect freedom by vibration, invariably takes the polarity of the external directing influence, such as that of the earth, and it does so even with greater freedom under the influence of heat. Manufacturers of electromagnets for telegraphic instruments are very careful to choose the softest iron and thoroughly anneal it; but very few recognise the importance as regards the position of the iron whilst annealing it under the earth's directing influence. The fact, however, has long since been observed.

Dr. Hooke (1684) remarked that steel or iron was magnetised when heated to redness and placed in the magnetic meridian. I have slightly varied this experiment by heating to redness three similar steel bars, two of which had been previously magnetised

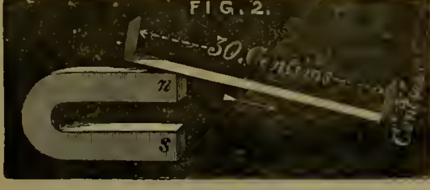
to saturation, and placed separately with contrary polarity as regards each other, the third being neutral. Upon cooling, these three bars were found to have identical and similar polarity. Thus the molecules of this most rigid material, cast steel, had become free at red heat, and rotated under the earth's magnetic influence, giving exactly the same force on each; consequently the previous magnetisation of two of these bars had neither augmented nor weakened the inherent polarity of their molecules. Soft iron gave under these conditions by far the greatest force, its inherent polarity being greater than that of steel.

I have made numerous other experiments bearing upon the question of neutrality, but they all confirm those I have cited, which I consider afford ample evidence of the symmetrical arrangement of neutrality.

Superposed Magnetism.—Knowing that by torsion we can rotate or diminish magnetism, I was anxious to obtain by its means a complete rotation from north polarity to neutrality, and from neutrality to south polarity, or to completely reverse magnetic polarity by a slight right or left torsion.

I have succeeded in doing this and in obtaining strong reversal of polarities by superposing one polarity given whilst the rod is under a right elastic torsion, with another of the opposite polarity given under a left elastic torsion, the neutral point then being reached when the rod is free from torsion. The rod should be very strongly magnetised under its first or right-hand torsion, so that its interior molecules are rotated, or, in other words, magnetised to saturation; the second magnetisation in the contrary sense and torsion should be feebler, so as only to magnetise the surface, or not more than one-half its depth: these can be easily adjusted to each other so as to form a complete polar balance of force, producing, when the rod is free from torsion, the neutrality as shown at B, Fig. 1.

The apparatus needed is simply a good compound horseshoe permanent magnet, 15 centimetres long, having six or more plates, giving it a total thickness of at least 3 centimetres. We need a sufficiently powerful magnet, as I find that I obtain a more equal distribution of magnetism upon a rod or strip of iron by drawing it lengthwise over a single pole in a direction from



that pole, as shown in Fig. 2; we can then obtain saturation by repeated drawings, keeping the same molecular symmetry in each experiment.

In order to apply a slight elastic torsion when magnetising rods or wires, I have found it convenient to attach two brass clamp keys to the extremities of the rods, or simply turn the ends at right angles, as shown in the following diagram, by which mean we can apply an elastic twist or torsion whilst drawing the rod over the pole of the permanent magnet. We can thus superpose several and opposite symmetrical structures, producing a polar north or south as desired, greatly in excess of that possible under a single or even double magnetisation, and by carefully adjusting the proportion of opposing magnetisms so that both polarities have the same external force, the rod will be at perfect external neutrality when free from torsion.

If we now hold one end of this rod at a few centimetres distance from a magnetic directive needle, we find it perfectly neutral when free of torsion, but the slightest torsion right or left at once produces violent repulsion or attraction, according to the direction of the torsion given to the rod, the iron rod or strips of hoop-iron which I use for this experiment being able, when at the distance of 5 centimetres from the needle, to turn it instantly 90° on either side of its zero.

The external neutrality that we can now produce at will is absolute, as it crosses the line of two contrary polarities, being similar to the zero of my electric sonometer, whose zero is obtained by the crossing of two opposing electric forces.

This rod of iron retains its peculiar powers of reversal in a remarkable degree, a condition quite different to that of ordinary magnetisation, for the same rod, when magnetised to saturation under a single ordinary magnetism, loses its evident magnetism by a few elastic torsions, as I have already shown; but when it is magnetised under the double torsion with its superposed magnetism, it is but slightly reduced by variations or numerous torsions, and I have found it impossible to render this rod again free from its double polar effects, except by strongly remagnetising it to saturation with a single polarity. The superposed magnetism then becomes a single directive force, and we can then by a few vibrations or torsions reduce the rod to its ordinary condition.

The effects of superposed magnetism and its double polarity I have produced in a variety of ways, such as by the electro-magnetic influence of coils, or in very soft iron simply by the directive influence of the earth's magnetism, reversing the rod and torsions when held in the magnetic meridian, these rods when placed magnetic west showing distinctly the double polar effects.

It is remarkable, also, that we are enabled to superpose and obtain the maximum effects on thin strips of iron from a quarter to half a millimetre in thickness, whilst in thicker rods we have far less effect, being masked by the comparatively neutral state of the interior, the exterior molecules then reacting upon those of the interior, allowing them to complete in the interior their circle of attractions.

I was anxious to obtain wires which would preserve this structure against the destructive influence of torsion and vibrations, so that I could constantly employ the same wires without the comparatively long and tedious process of preparation. Soft iron soon loses the structure or becomes enfeebled under the constant to and fro torsions requisite where we desire a constant change of polarity, as described later in the magnetic bells. Hard steel preserves its structure, but its molecular rigidity is so great that we obtain but mere traces of any change of polarity by torsion. I have found, however, that fine cast drill steel, untempered, of the kind employed by watchmakers, is most suitable: these are generally sold in straight lengths of 30 centimetres. Wires 1 millimetre in diameter should be used, and when it is desired to increase the force several of these wires, say nine or ten, should be formed into a single rod or bunch.

The wire as sold is too rigid to give its maximum of molecular rotation effect. We must therefore give it two entire turns or twists to the right, and strongly magnetise it on the north pole of the magnet whilst under torsion. We must again repeat this operation in the contrary direction, after restoring the wire to its previous position, giving now two entire turns to the left and magnetising it on the south pole. On restoring the wire to its original place it will be extremely flexible, and we may now superpose several contrary polarities under contrary torsions, as already described.

The power of these wires, if properly prepared, is most remarkable, being able to reverse their polarity under torsion, as if they were completely saturated; and they preserve this power indefinitely if not touched by a magnet. It would be extremely difficult to explain the action of the rotative effects obtained in these wires under any other theory than that which I have advanced; and the absolute external neutrality that we obtain in them when the polarities are changing, we know from their structure to be perfectly symmetrical.

I was anxious to show, upon the reading of this paper, some mechanical movement produced by molecular rotation, consequently I have arranged two bells that are struck alternately by a polarised armature put in motion by the double polarised rod I have already described, but whose position, at 3 centimetres distant from the axis of the armature, remains invariably the same. The magnetic armature consists of a horizontal light steel bar suspended by its central axle; the bells are thin wine glasses, giving a clear musical tone loud enough, by the force with which they are struck, to be clearly heard at some distance. The armature does not strike these alternately by a pendulous movement, as we may easily strike only one continuously, the friction and inertia of the armature causing its movements to be perfectly dead-beat when not driven by some external force, and it is kept in its zero position by a strong directive magnet placed beneath its axle.

The mechanical power obtained is extremely evident, and is sufficient to put the sluggish armature in rapid motion, striking the bells six times per second, and with a power sufficient to produce tones loud enough to be clearly heard in all parts of the hall of the Society. As this is the first direct transformation of molecular motion into mechanical movement, I am happy to show it on this occasion.

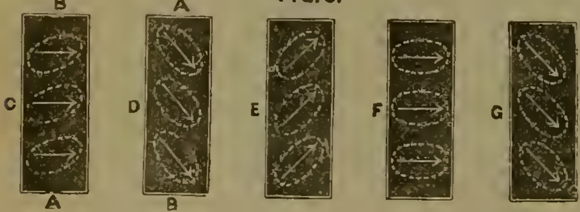
There is nothing remarkable in the bells themselves, as they evidently could be rung if the armature was surrounded by a coil, and worked by an electric current from a few cells. The marvel, however, is in the small steel superposed magnetic wire producing by slight elastic torsions from a single wire, 1 millimetre in diameter, sufficient force from mere molecular rotation to entirely replace the coil and electric current.

Elastic Nature of the Ether surrounding the Magnetic Molecules.—During these researches I have remarked a peculiar property of magnetism, viz., that not only can the molecules be rotated through any degree of arc to its maximum, or saturation, but that, whilst it requires a comparatively strong force to overcome its rigidity or resistance to rotation, it has a small field of its own through which it can move with excessive freedom, trembling, vibrating, or rotating through a small degree with infinitely less force than would be required to rotate it permanently on either side. This property is so marked and general that we can observe it without any special iron or apparatus.

Let us take a flat rod of ordinary hoop-iron, 30 or more centimetres in length. If, whilst holding this vertically, we give freedom to its molecules by torsions, vibrations, or, better still, by a few blows with a wooden mallet upon its upper extremity, we find, as is well known, that its lower portion is strongly north, and its upper south. If we reverse this rod, we now find it neutral at both extremities. We might here suppose that the earth's directing force had rotated the molecules to zero or transversely, which in reality it has done, but only to the limit of their comparatively free motion; for if we reverse the rod to its original position, its previous strong polarity reappears at both extremities, thus the central point of its free motion is inclined to the rod, giving by its free motion great symmetrical inclination and polarity in one direction, but when reversed the inclination is reduced to zero.

In Fig. 3 D shows the bar of iron when strongly polarised by earth's magnetic influence, under vibrations, with a sufficient

FIG. 3.



force to have rotated its elastic centre of action. C shows the same bar with its molecules at zero, or transversal, the directing force of earth being insufficient without the aid of mechanical vibration to allow them to change. The dotted lines of D suppose the molecule to be in the centre of its free motion, whilst at C the molecules have rotated to zero, as they are prevented from further rotation by being at the extreme end of its free motion

If, now, we hold the rod vertically, as at C, giving neutrality, and give a few slight blows with a wooden mallet to its upper extremity, we can give just the amount of freedom required for it to produce evident polarity, and we then have equal polarity no matter which end of the bar is below, the centre of its free rotation here being perfect, and the rod perfectly neutral longitudinally when held east and west. If, on the other hand, we have given too much freedom by repeated blows of the mallet, its centre of free motion becomes inclined with the molecules, and we arrive at its first condition, except that it is now neutral at D and polarised at C. From this it will be seen that we can adjust this centre of action, by vibrations or blows, to any point within the external directing influence.

We can perceive this effect of free rotation in a limited space in all classes of iron and steel, being far greater in soft Swedish iron than in hard iron or steel. A similar phenomenon takes place if we magnetise a rod held vertically in the direction of earth's magnetism. It then gives greater polarity than if magnetised east or west, and if magnetised in a contrary sense to earth's magnetism, it is very feebly magnetised, or, if the rod is perfectly soft, it becomes neutral after strong magnetisation. This property of comparative freedom, and the rotation of its centre of action, can be demonstrated in a variety of ways. One remarkable example of it consists in the telephone. All those who are thoroughly acquainted with electro-magnetism and know that it requires measurable time to charge an electro-magnet to saturation (about one-fifteenth of a second for those employed in telegraphy), were surprised that the telephone could follow the slightest change of timbre, requiring almost innumerable changes of force per second. I believe the free rotation I have spoken of through a limited range explains its remarkable sensitiveness and rapidity of action, and, according to this view, it would also explain why loud sounding telephones can never repeat all the delicacy of timbre that is easily done with those only requiring a force comprised in the critical limits of its free rotation. This property, I have found, has a distinct critical value for each class of iron. and I propose soon to publish researches upon the molecular construction of steel and iron, in which I have made use of this very property as a guide to the quality of the iron itself.

The elastic rotation (in a limited space) of a molecule differs entirely from that known as mechanical elasticity. In perfectly soft iron we have feeble *mechanical* elasticity, whilst in tempered steel we have that elasticity at its maximum. The contrary takes place as regards *molecular* elasticity. In tempered steel the molecules are extremely rigid, and in soft iron its molecular elasticity is at its maximum. Its free motion differs entirely from that given it by torsion or stress. We may assume that a molecule is surrounded by continuous ether, more of the nature of a jelly than of that of a gas: in such a medium a molecule might freely vibrate through small arcs, but a rotation extending beyond its critical limit would involve a much greater expenditure of force.

The discovery of this comparatively free rotation of molecules, by means of which, as I have shown, we can (without in any degree disturbing the external mechanical elasticity of the mass) change the axes of their free motion in any direction desired, has led me into a series of researches which have only indirectly any relation with the theory of magnetism. I was extremely desirous, however, of finding an experimental evidence which in itself should demonstrate all portions of the theory, and the following experiment, I believe, answers this purpose.

Let us take a square soft iron rod, 5 millimetres in diameter by 30 or more centimetres in length, and force the molecules, by aid of blows from a wooden mallet, as previously described, to have their centres of free motion in one direction, the rod will (as already shown) have polarity at both ends, when held vertically; but if reversed, both ends become completely neutral.

If now we turn the rod to its first position, in which it shows strong polarity, and magnetise it whilst held vertically, by drawing the north pole of a sufficiently powerful permanent magnet from its upper to its lower extremity, we find that this rod, instead of having south polarity at its lower portion, as we should expect from the direction of the magnetisation, is completely neutral at both extremities, but if we reverse the rod, its fullest free powers of magnetisation now appear in the position where it was previously neutral. Thus, by magnetisation, we have completely rotated its free path of action, and find that we can rotate this path as desired in any direction by the application of a sufficient directing power.

If we take a rod as described, with its polarities evident when held vertically, and its neutrality also evident when its ends are reversed in the same magnetic field, we find that its polarity is equal at both ends, and that it is in every way symmetrical with a perfect magnet. If we *gradually* reverse the ends and take observations of its condition through each degree of arc passed over, we find an equal symmetrical diminution of evident external polarity until we arrive at neutrality, when it has no external trace of inherent polarity, but its inherent polarity at once becomes evident by a simple return to its former position. Thus the rod has passed through all the changes from polarity to neutrality, and from neutrality to polarity, and these changes have taken place with complete symmetry.

The limits of this paper do not allow me to speak of the numerous theoretical evidences as shown by the use of my induction balance. I believe, however, that I have cited already experimental evidences to show that what has been attributed to coercive force is really due to molecular freedom or rigidity; that in inherent molecular polarity we have a fact admitted by Coulomb, Poisson, Ampère, De la Rive, Weber, Du Moncel, Wiedermann, and Maxwell; and that we have also experimental evidence of molecular rotation and of the symmetrical character of polarity and neutrality.

The experiments which I have brought forward in this paper,

in addition to those mentioned in my paper read before the Royal Society, will, I hope, justify me in having advanced a theory of magnetism which I believe in every portion allows at least experimental evidences of its probable truth.

THE REDE LECTURE

THE following abstract report of Prof. Huxley's Rede Lecture given on Tuesday week in the Cambridge Senate House, to a crowded audience, has been revised, to the extent of removing any errors of importance, by the author. We understand that a full report of the lecture will shortly be published in a separate form.

Professor Huxley said he had undertaken to treat in the course of such time as custom and the patience of his audience might permit, on a very great subject, no less a subject than the origin of all those forms of animal life which at present existed. It had behoved him to restrict what he might lay before them to those considerations which were absolutely essential for his purpose, and he should endeavour to lay before them facts of such an order as appeared to him to be of most importance in reference to his argument. Although he might fail to put those facts before them as clearly as they presented themselves to his own mind, the reasonings which might be based upon them were of so simple an order that he should consider his task performed if he gave them a tolerably clear conception of what those facts were, for he did not think it was the business of a man of science to use the arts of rhetoric or endeavour to procure persuasion. His sole business was to place the facts before those whom he wished to teach, and to leave it to their reason to form such judgment upon those facts as they might think fit. In the present case he should point out to them what judgments such facts had forced upon his mind, but he must leave it entirely to their responsibility to say what judgment they might constrain them to give in their case. They might assume this position at starting, that, whatever in such a matter was true for one animal, was true for the infinite series of the whole animal world; and as he was extremely anxious to avoid everything speculative, everything that could not be directly led back to the matters of fact upon which it was based, he proposed to select one animal particularly, and to put before them facts and arguments by the help of which they might form some probable conclusion as to the origin of that object. He took it for granted that, if the evidence inclined towards a particular conclusion in the case of that animal, they might assume that it would incline in the same direction with regard to all. He had no doubt that a great many of his audience were familiar at any rate with the shell of the animal about which he was going to speak, namely, that of the pearly nautilus, from which, or parts of which, very beautiful ornaments were fabricated. At the present time the nautilus inhabited the warmer parts of the Indian and Pacific Oceans, living at considerable depths and preying upon the hard shelled crustaceans and mollusks that crept along the bottom, and which it found in its way. For that end it was provided with a very curious beak, shaped like that of a parrot, but with each portion covered with a hard calcareous deposit, and which enabled it to be an efficient instrument for crushing its prey. If he were to touch upon the morphological problem which here presented itself, he could occupy far more time than they had at their disposal with the consideration of a multitude of interesting peculiarities which the nautilus presented, for it was one of those forms which at present stood almost isolated and alone in the animal world, separated by a wide gulf from its nearest allies, those animals which they knew as squids and cuttle-fishes. It held the middle place between sea-snails and the group of the cuttle-fishes. It would be, however, entirely out of place at present, and a purposeless waste of time if he were to touch upon any peculiarities except those which would be needed during his further argument. The only points to which he would direct their attention for that purpose were the facts which related to the structure of the shell. There was a diagram beside him showing a part of the nautilus shell in section, but he thought it possible that he could make the matter clearer by roughly sketching on the board the main points as he went on.—Prof. Huxley here described, with the aid of diagrams, preserved specimens, and models, the complicated structure of the shells of the pearly nautilus, or *Nautilus pompilius*. The animal itself was contained in the spacious chamber in the outer part of the shell, which was divided from the rest of the shell by a partition. The rest of the shell resembled a long cone closely coiled up, and divided by partitions at regular intervals into other chambers, which succeeded one another, and in the full-grown animal were full of air. From the hinder part of the animal's body a long tube, the siphuncle, was carried backwards through the whole of the shell, and as it completely filled up the openings in the partitions through which it passed there was no communication between one chamber and another. The first point to be considered was as to what was the origin of the particular nautilus in the bottle before him. Happily there was no dispute upon that point. The female nautilus contained eggs exactly as the hen did. These eggs were small masses of protoplasmic matter, each containing a nucleus in its centre, which was all that was essential. They knew that that pearly nautilus with all its complicated organism, and fitted with the complicated shell he had described, did, in some way or other, proceed from that relatively structureless body which they called the egg or the ovum. As fate would have it, up to the present they had known nothing from direct observation of the process by which that particular animal was produced from this microscopic particle. But they had so large a knowledge of the process in other animals of every description that there was no doubt whatever as to the nature of the process, which he would try to describe to them as briefly as possible, by reference to the process which took place in the case of the domestic hen. Neither by the highest powers of the microscope, nor by other means of investigation which they had at present, could they trace anything in the slightest degree resembling either the chick, which under certain circumstances proceeded from that egg, or the tissues of the chick. There was, however, one spot on the yolk of the egg, a little careful observation of which would show a clear space, which might be a fifth of an inch in diameter. It was very well known by the name of the cicatricula, or little scar. He would suppose that twenty-one eggs were placed together under the hen. If they took one egg day by day and examined it they would know what took place as if they had watched continuously, for what happened in any one egg happened also in the others. That was a process—the wonder of which he must confess never staled in his mind—by which the chick was gradually fashioned out of that transparent rudiment. They saw it make its appearance in the first place on the surface of the yolk, and to the naked eye it looked like a white streak. That white streak gradually assumed the appearance of a sort of elongated body, and that body shaped itself so that it could be seen that it was going to be an animal of some kind, it having a large head, and the rudiments of eyes and vertebræ. On the fifth day they could clearly see what they were going to have. Gradually, step by step, and moment by moment, new differences made their appearance from the original foundation, and until many days before hatching there was an unmistakable bird, and at the twenty-first day there emerged from the shell an animal endowed with all a bird's capacities and structures. That process was the process of development. If they inquired into the nature of the cicatricula, they would find that that was merely a double layer of minute nucleated cells. They would find that that resulted from the splitting up of a protoplasmic mass that had been there before. They could trace the process back into the body of the hen until they came down to a simple nucleated cell, so that it was a matter capable of demonstration that in that nucleated cell which formed a part of the egg organ of the hen—in that particle of, for morphological purposes, structureless jelly, were the same characteristics which were possessed by the very lowest forms of animal life which were known. They knew that in that particle resided a potentiality, capable of developing itself through the stages he had roughly indicated, until it became not only a machine of the highest order from a physiological point of view, but a very remarkable work of art. That particle of protoplasmic matter did that in virtue of the powers inherent in its material nature. That was the point he wished to put before them as clearly and definitely as he could, because it would be fundamental in all further discussion. For it was to the process he had briefly described that the great discoverers of the last two centuries applied the name of "evolution." Singularly enough the persons who first used that name did not use it in that sense in which it was universally used now, because they were under a mistake as to the exact nature of the process. But the whole conception of evolution was now based upon ascertained facts, showing the process of development of the most complicated animal out of a relatively structureless particle, which had no higher organisation than that of the

lowest animal they knew, a process which progressed step by step by means of the gradual addition of small differences, until the animal attained its perfect form. That was what was meant by the process of evolution. At this point he thought it might be desirable that he should deal with what he might speak of as the *a priori* objections to the doctrines of evolution. He had had opportunities of making extensive acquaintance with those objections during the past twenty years or so. He divided them into three categories: (1) That evolution was impossible; (2) that it was immoral; and (3) that it was opposed to the argument of design. Now that was a very heavy indictment, but he thought they must plead "not guilty" upon all three counts. It required no great amount of reasoning to convince one that that which happened could not be impossible; that that which happened thousands and millions of times every hour and every minute in this world as it now was, under certain conditions, could not be held without further evidence to be impossible under somewhat different conditions. Secondly, with regard to the question of morality. He had never understood that argument, and had always been disposed to reply that the morality which opposed itself to truth committed suicide. With regard to the argument of design he would not discuss that point himself, but would beg them to listen for a moment to words that would carry far more weight than any of his own could carry on that topic:—"The philosopher beholds with astonishment the production of things around him. Unconscious particles of matter take their stations and severally range themselves in an order so as to become collectively plants or animals, *i.e.* organised bodies with parts bearing strict and evident relation to one another and to the utility of the whole; and it should seem that these particles could not move in any other way than they do, for they testify not the smallest sign of choice, or liberty, or discretion. There may be particular intelligent beings guiding their motions in each case, or they may be the results of trains of mechanical dispositions fixed beforehand by intelligence or appointment and kept in action by a power at the centre." They might imagine, and not unreasonably, that those were the words of some ultra-evolutionist of the present day who desired to set himself right with the argument from design; but they were not so. They were more than eighty years old, and they were contained in the 23rd chapter of a book which was very much talked about, but, he was afraid, very little read, namely, the "Natural Theology" of Archdeacon Paley. When he was a boy that book was a very great favourite of his, partly for its own merits, and partly because it was one of the few books he was allowed to read on Sundays. He found it much more entertaining than most of the books included in that category. But from what had been since said of the Atheistic tendencies of the doctrine of evolution he began to think that he stood before them a miserable example of the manner in which a man's mind might be poisoned by early instruction, and that his incapacity to understand the force of the arguments against evolution arose from the circumstance that in his early childhood he was indoctrinated with the reasonings of a great divine of the Church.—Professor Huxley now proceeded to consider the next point, the coming into existence of the nautilus species in contradistinction from the origin of a particular nautilus as an individual. He showed that, according to all the evidence that could be gathered, there was every reason to believe the forms of animal life five thousand years ago were practically the same as they were now. If there were no other means of knowing anything about the history of animal life, undoubtedly this experience, resting upon a duration of five thousand years, would have furnished an apparently sufficient basis for a generalisation, tending to the conclusion that the forms of animal life had not changed during that period. Not only had that generalisation been made, but it had been concluded that the forms of animal life were unchangeable, a totally different proposition, the validity of which rested, among other things, on the proportion between our actual experience, supposing it to extend over that time, and our possible experience of the duration of life on the globe. It would, he thought, be absolutely impossible for any of them, however good their vision, to say from actual observation of the hour hand of a watch for four seconds that it had moved during that interval, and in point of fact the space over which it would move was so minute as to be indiscernible, even through a magnifying glass. Yet they knew very well that it had moved, and if they watched it for four or five minutes, the evidence of its movement would be perfectly obvious, even to the naked eye. They would observe, therefore, that a period of observation which extended over the nine-hundredth part of an hour, would give them no conception from which it would be possible to draw a conclusion as to what had happened during the total period. Now geologists told them that the whole depth and extent of the fossiliferous rocks, which composed a considerable portion of the earth's crust, represented a period of time at least one thousand times as great as the historical period. That was a point upon which there could be no room for hesitation. Hence it followed that when they acquainted themselves with the succession of animal forms which were embedded at different depths in the earth's crust, they did exactly what the observer of a watch did when he kept his eyes fixed on it, not for four seconds but for an hour, in which latter case the movement was not only conspicuous, but such as commonly served to indicate the lapse of time. If that analogy held good, the slow procession of events which might be absolutely indiscernible in the course of 5,000 years, would become obvious and plain when the period of observation was extended to a thousand times that period. And that was exactly what happened, for if they went back in the series of stratified rocks they found the genus nautilus, which in the present day was represented by one or two species, represented in the long period of its history by many other species. As far back as the Upper Silurian formation the genus nautilus was represented by an abundant number of shells fabricated by animals having all the essential peculiarities which he had described. In the geological specimens before him, and which were taken from the rich collection in the Woodwardian Museum, there were forms of nautili which no one doubted were to all intents and purposes the same in their general structure as the pearly nautilus of the present day, although they were at least 5,000,000 years old. Now came the main question: were those nautili whose history extended back through such a prodigious range of time identical in character with the modern species? So far as he knew there was nothing in the nature of things to show why a succession of generations which remained unchanged through 5,000 years should not remain so for 50,000 or 50,000,000 years. The facts, however, showed that there had been rather more than 100 distinct species of nautilus, each having as good a title to be called a species as *Nautilus pompilius* itself. No one of these species had endured for more than a portion of the duration of the whole genus, and many species had existed contemporaneously, those species, however, except perhaps two, were now extinct, so that now they were brought face to face with the heart of the question: by what hypothesis could they account for those phenomena? They were driven into hypothesis of some kind or other, because it was impossible to have any evidence of contemporary witnesses of facts which went so far back into the past. So far as he knew there were only two possible alternative hypotheses by which they could pretend to account for those facts. One of these hypotheses was what he ventured to call the hypothesis of construction. That hypothesis was that every one of those species was put together. It was making a needless difficulty to suppose that each species came out of nothing, because they knew that the body of the nautilus was made up of materials which were familiar to them in an inorganic state on the earth's surface; so that by the hypothesis of construction some agency had put together those materials a hundred times or so during the period that had elapsed from the formation of the Silurian rocks to the present day, as an artist constructed his work, or as a mechanician put together the parts of his machine. That was one hypothesis. For his part, he had not a word to say *a priori* against the possibility of that hypothesis. It was certainly conceivable and therefore, according to Hume's maxim, it was possible. But they must bring it, like all other hypotheses, to the test of facts and inquire how far it stood that test. He thought the hypothesis of construction presented two large and almost insuperable difficulties. The one was that it was absolutely opposed to everything that they had received traditionally concerning the origin of animal forms, and the second was that it was no less opposed to every doctrine which might reasonably be held upon grounds of sane science. It stood to reason and common sense that they could have recourse only to those causes for the assumption of which there was some ground of analogy. The business of science would be extremely easy if for every event one were permitted to invent special causes having no analogy in nature. The difficulty of science was in tracing every event to those causes which were in present operation. That difficulty was being so constantly overcome that it had become a canon of

physical science no less than it was a canon of historical science that speculation should confine itself to construing past events by the analogy of those of the present time. The hypothesis of construction seemed to him unacceptable, because it led them into contravention of tradition on the one side and into contravention of scientific logic on the other. The only other alternative hypothesis was that of evolution, which meant that the different forms of animal life had not arisen independently of each other in the great sweep of past time, but that the one had proceeded from the other; and that that which had happened in the course of past ages had been analogous to that which took place daily and hourly in the case of the individual. That was to say that just as at the present day in the course of individual development the lower and simple forms, in virtue of the properties which were inherent in them, passed step by step by the establishment of small successive differences into the higher and more complicated forms, so, in the case of past ages, that which constituted the stock of the whole ancestry had advanced grade by grade and step by step until it had attained the degree of complexity which was seen at the present day. No objection could be brought against this hypothesis on the ground of analogy, because in putting it forward they were not bringing in any kind of causation which was not abundantly operative at the present time. The question was whether the history of the globe in past time coincided with this hypothesis, and to that point he would next address himself. What did they find if they considered the whole series of these forms? Unquestionably, as he had said, nautili were found as far back as the Upper Silurian age. Before that time there were no nautili, but there were shells of the *Orthoceratidæ*—of which there were magnificent examples before him—which resembled those of the nautili in that they were chambered, siphoned, &c., with the last chamber of such a size that it obviously sheltered the body of the animal. He thought no one could doubt that the creatures which fabricated these still earlier shells were substantially similar to the nautili, although their shells were straight, just as a nautilus shell would be if it were pulled out from a helix into a cone. Then came the forms known as the *cyrtoceras*, which were slightly curved. Along with these they had the other forms which were on the table, and in which the shell began to grow spiral. The next that came were forms of nautilus, which differed from the nautilus of to-day in that the *septa* were like watch-glasses, and that the whorls did not overlap one another. In the next series, belonging to the later palæozoic strata, the shell was closely coiled and the *septa* began to be a little wavy, and the whorls began to overlap one another. And this process was continued in later forms, down to that of the present day. Looking broadly at the main changes which the nautilus stock underwent, changes parallel with those which were followed by the individual nautilus in the course of its development, he considered that there could be no doubt that they were justified in the hypothesis that the causes at work were the same in both cases, and that the inherent faculty, or power, or whatever else it might be called, which determined the successive changes of the nautilus after it had been hatched, had been operative throughout the whole continuous series of existence of the genus from its earliest appearances in the later Silurian rocks up to the present day. What the whole question, in whatever way it might be put, came to, was this: Successive generations of animals were so many cycles of evolution that succeeded one another. Within the historical period, there was no doubt that, speaking roughly, those succeeding cycles had been identical, that was to say, without discernible difference. But when the period of observation became proportional to the slow rate of change they found, so to speak, that the hour hand had moved; for, in the successive cycles of evolution which had occupied the whole period, successive cycles had differed from one another to a slight extent. If they might assume that, then the whole of the phenomena of palæontology would fall into order and intelligibility. If not, they had to adopt an hypothesis which, as he had pointed out, had no support in tradition, and which was absolutely contradicted by every sound canon of scientific research. This was his case for evolution, which he rested wholly upon arguments of the kind he had adduced. From the time when he first read Charles Darwin's "Origin of Species," now some twenty-four years ago, his mind had fixed itself upon the tenth chapter of that book, which treated of the succession of forms in geological times, for it appeared to him that that was the key of the position; that if the doctrine of evolution was correct, the facts of palæontology, as soon as they became sufficiently known, must bear it out and verify it in every particular. On the other hand, he believed that, if the facts of palæontology or the historical facts of life on the globe were against evolution, then all the rest of the argumentation in its favour would be vain and empty, because the difficulty of adopting it would be in that case absolutely insuperable. He would venture to repeat that the occurrence of evolution was a question of history. He did not know whether Sir Henry Maine was not more competent to speak on that point than he was. It was a question as to whether they would interpret the facts of animated nature scientifically, or whether they would open the door to every description of hypothetical vagary. He came to the conclusion that that was a point worth testing in every possible way, and for some twenty years he had given what leisure he had been able to beg, borrow, or sometimes steal, to the investigation of these questions. He had endeavoured to ascertain for himself how the doctrine of evolution fitted with the facts of palæontology, with regard to the higher vertebrated animals, and with regard to the chief varieties of invertebrate animals, and all he could tell them was that the farther his own investigations had gone, the more complete had appeared to be the coincidence between the facts of palæontology and the requirements of the doctrine of evolution. The conclusion he had come to was that at which every competent person who had undertaken a similar inquiry had arrived, and if they would pay attention to the writings of such men as Gaudry, Rütimeyer, Marsh, Cope, and others, who had added materials upon which to form a judgment such as were not dreamt of when Darwin first wrote, they would find that they all without hesitation attached themselves to the doctrine of evolution as the only key to the enigma. In deciding the issue between the two hypotheses, serious inquirers would not trouble themselves about any collateral points as to the how and the why, or as to any of the subordinate points at issue. He thought he was entitled to entreat those who by their calling or by their position in society, or by the fact that they possessed any influence, might be led to express an opinion upon this matter, to look into the arguments which formed the foundation of the case for evolution. Happily, he might address that recommendation to members of the University of Cambridge with a perfectly good conscience, for at this present time he knew not where in the world any one could find better means of passing through all those preliminary studies which were essential to a comprehension of this great question, or where any one could find more amply displayed the means of testing the arguments which he had laid before them. He ventured to say that the members of this University were without excuse if they gave opinions on this question of evolution without having prepared themselves, by as diligent study as they would for the purpose of approaching questions of literary or theological criticism, to express an opinion upon it. These were the considerations which he had wished to set before them that day. It would be understood that they would not suffice to enable any one to form a judgment upon the doctrine of evolution, but he hoped that they had sufficed, brief and insufficient as they were, to show that if judgment on this question was to be worth anything intellectually, if it was to be creditable to the moral sense of those who formed it, it would first be necessary that the facts should be clearly comprehended, and that the conclusion—whatever it might be—should be one which right reason would admit might be justly and perfectly connected with the facts.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE

OXFORD.—The term that has just concluded has been chiefly noticeable for the interest drawn towards Oriental studies in the University by the building of the new Indian Institute. The visit of the Prince of Wales to the Chancellor of the University served to draw national attention to the work which Oxford, and especially Balliol College, has undertaken in respect to the training of the selected candidates for the Indian Civil Service. In spite of the failure of the late attempt to induce the University to relax its rule requiring three years' residence as a qualification for a B.A. degree in the case of the Indian Civil Servants, a considerable proportion of the selected candidates come into residence at the University; Balliol, by providing teachers and tutors in Oriental subjects, attracts by far the greatest number.

With the exception of two debates there has been little excitement during the term in the Convocation House. The two questions that roused general interest were, first, the proposal that

examiners in the Pass Schools should allow merit in one subject to compensate for a deficiency in another; and secondly, the decree to grant 10,000*l*. to Prof. Burdon Sanderson for the equipment of the new Physiological Laboratories. In the first debate the proposal was only carried by the casting vote of the Vice-Chancellor, and some doubt has since been raised on the qualification of one of the voters. In the second debate the opponents of vivisection, allied with those who oppose any large expenditure by the University on economic grounds, sought to throw out the decree and force the University to make special provision against the Professor experimenting on living animals. Prof. Burdon Sanderson in his speech disclaimed any intention of introducing vivisection into his courses or demonstrations, but declared that he would experiment on living animals in his own researches if he deemed it necessary for the discovery of truth. The decree was carried in a large house by 88 votes to 85.

The Commemoration in the Sheldonian Theatre passed off with less uproar this year. Among the recipients of honorary degrees Lord Rayleigh and Sir Frederick Abel represented Science.

In November next Balliol and Christ Church will hold examinations for electing to Natural Science Scholarships. The subjects at both colleges will be Chemistry, Physics, and Biology, with an essay and an optional paper in Mathematics.

CAMBRIDGE.—The Senior Wrangler in the Mathematical Tripos (Parts I. and II.) is Mr. Mathews, of St. John's College; Mr. Gallop is second; Mr. Lachlan, third; Messrs. Chevallier and A. N. Whitehead, bracketed fourth—all of Trinity College. One lady, Miss Perrin, of Girton, is placed between the 20th and 21st Wranglers. Three ladies are senior optimes; one is junior optime.

The Special Board for Mathematics have recommended that the Smith's Prize be awarded for the best essay on any subject in Mathematics or Natural Philosophy, to be sent in about a year and a half after the candidates are of standing for Parts I. and II. of the Mathematical Tripos; and that the adjudicators be the Vice-Chancellor, the Mathematical Professors, and the Cavendish Professor.

Prof. Foster has given notice of a revision class in Physiology during the Long Vacation, to be held at the Physiological Laboratory.

The proposed regulations for the Balfour Fund have been formally adopted by the senate.

The annual report of the Observatory states that, owing to the great progress made with the zone observations it has been possible to give much attention to the comets of recent years, and important contributions to the computations of their orbits have been made by the Observatory.

The General Board of Studies have published their recommendations with regard to new teachers, buildings, and appliances, and it is at once evident that several times the whole amount of the new income of the University could readily be spent in supplying the distinct wants of the several departments. They confine their recommendations as to Readerships within narrow limits owing to the extreme pressure upon University Funds, but they recommend the appointment of the present Readers in Indian Law, Classical Archæology, and Talmudic Literature as University Readers at 300*l*., not 400*l*. as proposed by the Statutes, a Reader in Comparative Philology at 300*l*. and a Reader in Botany at 100*l*. a year, tenable with a College Lectureship. As to University Lecturers, that is College Lecturers who throw open some of their lectures to the University and give advanced lectures, they recommend, as regards Medicine, four University Lecturers; Mathematics, five; Biology—one in Botany, one in Zoology; three in Physiology; two at least in Geology; and others in other departments.

More Demonstrators, the senior to be better paid than at present, are further recommended to be appointed in various departments of Natural Sciences.

The appointment of a Professor of Pathology is again pressed as urgent; provision to be made for a temporary laboratory.

As to buildings, the Board have placed among urgent requirements the extension of the buildings for Physiology and Comparative Anatomy, Chemistry, Botany, Mechanism, and for Geology, to be partly supplied by the Sedgwick Memorial Fund. As extra to the latter fund, 10,000*l*. is asked.

A special grant of 500*l*. for physiological apparatus is recommended. Further, the Museum and Lecture Rooms require at least 350*l*. more annually from the new funds, in addition to 500*l*. asked for from the ordinary income of the chest.

The cost of a chemical laboratory is provisionally estimated at 15,000*l*., and the purchase of Prof. Stuart's plant, with which he has at his own risk developed the flourishing school of engineering in the University, at 2,500*l*. Then permanent buildings for the school of Mechanism would cost 3,500*l*. more.

The recommendations of the General Board, after sifting and reducing the recommendations of the Special Boards, will entail annual charges of 4,360*l*., in addition to at least 2,500*l*. required by new professorships or new elections to existing professorships.

Capital expenditure will be required for buildings 31,200*l*., and for special grants other than building, 4,810*l*.; but it is proposed to borrow for these purposes. The Board have been informed that the special sum (500*l*.) asked for physiological apparatus will be provided by the liberality of a private donor who wishes to remain anonymous.

No voting can take place on these proposals till next term.

The special reports, on which the detailed Report of the General Board of Studies is founded, contain much interesting information about the present state of Natural Science studies in the University.

The Medical Board ask for provision for teaching in Medical Jurisprudence, Sanitary Science, Mental Diseases, and Elementary Medical and Surgical Methods. The number of students at present is about 200.

The report of the Classical Board contains an elaborate account of the present provision for studying Philology, Antiquities, Ancient Art, Topography, &c. which we cannot here reproduce.

The Board of Oriental Studies ask for University Lectures in Hebrew and Sanskrit, and for a Reader in Syriac, and that the Lord Almoner's Professor of Arabic be secured, if possible, as a resident professor by the augmentation of his stipend. They also urge the importance of establishing teaching in the departments of Egyptology and Assyriology.

The Mathematical Board estimate the resident students for Mathematical Honours as between 300 and 400. There are thirty-four College Lecturers in Mathematics, much of whose time is occupied in preparing candidates for the pass examinations. It will be impossible to secure adequate teaching of the subjects of Part III. of the Mathematical Tripos unless at least University Lecturers are appointed, and the Board ask for five at 50*l*. a year, two courses of advanced lectures being required from each lecturer every year.

The Board for Physics and Chemistry in addition to the laboratory claims press for additional means of catechetical teaching in Chemistry and instruction in Technical Electricity; in Mechanism a Superintendent of the Workshops, and in Mineralogy a Curator of the Museum. The number of students in Chemistry in the University is nearly 200; in Physics (Cavendish laboratory only), average for last two years, 54; Mechanism 42; Mineralogy 9.

The Board urge the advisability of Colleges permitting their lecturers in Chemistry and Physics to lecture in the University lecture rooms and laboratories, to allow more efficient organisation of teaching, as well as economy in expenses.

Lord Rayleigh asked for 600*l*. additional for Demonstrators in Physics, but the General Board of Studies have only recommended 220*l*. to be granted.

Professor Stuart's workshop has not more than half supported itself by fees of students as yet, but by employing the workmen in the manufacture of apparatus, &c., for other University departments after their hours of teaching, he has made a profit sufficient to pay the deficit, except the cost of demonstrators. A superintendent of the workshops is absolutely necessary if the University keeps up the school of Engineering, and a demonstrator in each department. Thus the Professor would not as now, be required to teach in the workshops and act as general manager as well as demonstrator. A considerably larger foundry is required, as the department has proved most useful.

The Board for Biology and Geology recommend the appointment of a Professor of Animal Morphology, and, failing this, three University Lecturers in this subject, one of whom shall direct the laboratory.

In relation to Physiology, Dr. Foster made an elaborate report, describing the organisation of, and work done in, his laboratory. He asked for a head demonstrator and four assistant demonstrators. As to advanced lectures, mention was made of the very largely unpaid work undertaken by Dr. Gaskell (entirely

unpaid), and Messrs. Langley and Lea, and University recognition of their work was asked for. Elementary Biology and Physiology of the Senses were also mentioned as needing a special lecturer.

With regard to Botany, teaching in Vegetable Morphology and in Physiology is urgently required, with lecture rooms and laboratories.

It is further asked that University teachers be eventually appointed in Agriculture, Anthropology, Geography, Metallurgy, and Mining.

In Geology it is pointed out that since Prof. Bonney left Cambridge, no College has given any assistance towards geological teaching, and that Dr. Roberts and the other demonstrators have received no University or College payments for the continued work they have done in lecturing and demonstrating.

The average number of students at present in the various departments of Biology and Geology is—Botany, 80; Geology, 40; Zoology, 75; Physiology, 120; Human Anatomy, 100 each term.

Donald MacAlister, M.D., M.B., Fellow and Medical Lecturer of St. John's College, Cambridge, was on Thursday, June 14, elected a member of the Council of the College.

The following awards have been made at St. John's College for proficiency in Natural Science:—Foundation Scholarships to Andrews, Kerr, Phillips (R.W.); Exhibitions to Goodman (already Scholar), Cooke, (E. H.), Fenton, Jones (H. R.), Watts; a Proper Sizarship to Gepp. Goodman obtains a Wright's Prize with augmentation of emoluments to 100*l.*, and a Hughes' Prize, as one of the two most distinguished third-year students in the College. The Open Exhibition was awarded to Rogers.

Mr. J. V. Jones, Principal of Firth College, Sheffield, has been elected by the Council to be the first Principal of the University College for South Wales and Monmouthshire.

SOCIETIES AND ACADEMIES

London

Royal Society, May 24.—"The Effects of Temperature on the Electromotive Force and Resistance of Batteries, II." By William Henry Preece, F.R.S.

In the discussion on the previous paper read on February 22, 1883, it was suggested that observations should be made on the influence of temperature to the case of secondary batteries. One of Mr. Tribe's cells was used.

The negative element of this cell consisted of pure peroxide of lead in the form of a plate 4 inches square carried in a grooved frame, from one end of which projected the necessary conductor. This element was placed between two plates of finely divided lead likewise 4 inches square. These were joined together, and formed the positive element of the cell. Each half of the positive plate was about a quarter of an inch distant from the negative, and all three plates were incased in a thin specially prepared fabric. The elements were contained in a leaden case, and the liquid was sulphuric acid of the strengths given in the various experiments. This cell was placed inside the cylindrical copper vessel used in the previous experiments, and precisely the same method of observation was adopted. The influence of heat on secondary cells was the same in kind as in the Daniell cell, but it differs very much in degree. The electromotive force practically remains constant for all degrees of temperature, but the internal resistance diminishes as the temperature increases at a very steady rate, increasing again as the temperature is lowered. The effect of varying the percentage of acid in solution is not very marked, though as might have been anticipated from Kohlrausch's observations, the 30 per cent. proportion gives the lowest resistance. The mean average reduction in resistance between 0° and 100° C., is 59·6 per cent.

Chemical Society, June 7.—Dr. Perkin, president, in the chair.—The following papers were read:—Laboratory notes by J. H. Gladstone and A. Tribe: (1) On the action of light and heat on cane and invert sugars; cane sugar solution, when heated, forms a small quantity of a substance which is not alcohol, but which gives the iodoform reaction. (2) On hydroxylamine; the copper zinc couple reduces this substance, ammonia being formed. (3) On the recovery of iodine from organic iodide residues; the residues are poured on to an excess of the couple, and the iodide of zinc formed, extracted with hot water; iodine is obtained in the free state by the action of hydrochloric acid and bleaching powder on the iodide. (4) A residual phenomenon of the electrolysis of oil of vitriol; the formation of Berthelot's persulphuric acid was noted. (5) On an alleged test for alcohol; Davy suggests that alcohol can be detected by the blue colour produced with a warm solution of molybdic anhydrid in oil of vitriol. The authors find that other reducing substances and sugar give the same reaction. (6) Reaction of the couple on nitric oxide; ammonia is formed, but no protoxide. (7) On the reducing action of spongy lead.—Note on a basic ammonio-copper sulphate, by S. U. Pickering.—Notes on Loew and Bokorny's researches on the probable aldehydic nature of albumin, by A. B. Griffiths.—Note on the action of sulphuric acid, sp. gr. 1·84, upon potassium iodide, by H. Jackson. The author has investigated this reaction quantitatively; he finds that two reactions occur, one with an excess of sulphuric acid when iodine and sulphur dioxide are formed; the second when just sufficient sulphuric acid is used to satisfy the potassium iodide; iodine and sulphuretted hydrogen are then liberated.—The action of nitrous anhydride on glycerin, by O. Masson. The author obtained the trinitrite of glyceryl; it is an amber-coloured liquid boiling at 150°, burns with a white flame, but does not explode under the hammer. It is decomposed by water, and cannot be preserved. In sealed tubes it generates sufficient gas to shatter the glass.

Linnean Society, June 7.—Sir John Lubbock, Bart., president, in the chair.—Mr. R. J. Clarke and Mr. Frank Matthews were elected Fellows of the Society.—Mr. W. T. Thiselton Dyer exhibited a series of Copals: some from Inhambane, near Mozambique, the product of *Copaifera Gorskiana* of various sorts, with a melting point from 310° to 360° Fahr.; others from Lagos (obtained by Capt. Moloney), used by the natives for burning, and powdered by the women as a body perfume. These last are supposed to be from a species of *Daniellia*, the native name being "Ogea."—Mr. Hiern drew attention to specimens of *Quercus Ilex*, var. *Fordii*, from Barnstaple, Devon, showing remarkable alteration in the leaves after pruning. There was exhibited for Mr. Stansfield R. Rake a burdock leaf with numerous excrescences, supposed to be the result of insect irritation.—Mr. G. Murray exhibited specimens of dace killed by the fungus disease (*Saprolegnia ferax*), the result of inoculation, and said to be the first recorded experimental proof of the communicability of the disease to those fish.—Dr. Cobbold showed shrimps sent by Dr. Burge of Shanghai. They contained immature flukes, which it was thought might prove to be the larval state of one or other of the three species of human fluke known to infest man in eastern countries. He proposed to call the parasite *Cercaria Burgei*.—A paper was read by Mr. H. N. Ridley, on new and rare monocotyledonous plants from Madagascar, among which may be mentioned species of *Drimia* hitherto only known from Africa, several curious orchids, one remarkable for possessing only one or two very large, handsome green, white, and purple flowers. Of Cyperaceæ one form well known as an Indian plant, another of the genus *Fintelmannia*, supposed to be confined to Brazil; he also describes a new genus, *Acriulus*, allied in some respects to *Cryptangium*.—A communication was read from Mr. George Lewis, on Japan Brenthidæ and notes of their habits. These beetles form part of the collection made by the author in his visit to Japan during the summers of 1880-81. He observes that there is no geographical barrier sufficient to exclude tropical forms from Japan, but their environment, when they reach it, prevents them from establishing themselves, to any great extent at least, in the northern parts. In the southern islands of the Japanese Archipelago the warmer climate enables a fair number of beetles of a truly tropical type to exist. The fact that each genus is only represented by one species nevertheless points to some physical check in their spread and numbers. A new genus, *Higonius*, is characterised, and several species of this and other genera described and illustrated.—Mr. T. H. Corry read a paper on the fertilisation of the Asclepiads, chiefly bearing out views noticed on a former occasion.—A short record of observations on the White Ants (Termites) of Rangoon, by Dr. Robert Romanis, was read by the Secretary. He details what he saw in what may be termed the swarming of a nest.

Edinburgh

Royal Society, June 4.—Mr. Thomas Gray, vice-president, in the chair.—Mr. Buchan read a second paper on the oscilla-

tions of the barometer, the conclusions of which were based largely on the *Challenger* observations. It appeared that the greatest diurnal oscillation occurred in regions over the sea where the air was very moist, being least indeed in those oceanic regions north and south of the equator where the average height of the barometer was greatest; whereas over land the contrary was the case, the greatest oscillations occurring where the air was driest. The explanation given was that over the ocean, whose surface changes very slightly in temperature throughout a whole day, the main effect results from the direct heating of the air and its contained moisture; while over the land the effect due to surface changes preponderates, being less, of course, the better the air acts as a screen to the solar rays, that is, the moister it is. Mr. Buchan then proceeded to account for the double maximum in the diurnal oscillations of the barometer. Beginning at six o'clock in the morning, an hour at which in general the barometer shows its daily mean, we find that the first effect of the sun is to heat the air, which tends to expand and rise. This tendency is of course somewhat resisted, so that the pressure is in the first instance increased; but by and by this resistance is overcome, the air flows freely upwards, the morning maximum is reached, and the pressure begins to fall. After noon this diminution in pressure is accelerated by the cooling of the air, for the same reason that the first effect of heating is to increase the pressure. Hence the barometer falls to its afternoon minimum. But as this is going on the region to the west is in its turn being heated, and an eastward movement of air overhead takes place towards the first locality, arresting the diminution of pressure, and then bringing it to a second maximum. This action, however, ceases as midnight comes on, the cooling of the air being then left to have its own effect, and the pressure falling to its second minimum till the approach of the sun on the east makes itself felt, and the same cycle of operations begins again. The modifications introduced by special conditions, such as the distribution of land and water, were also discussed, and explanations given of the retardation in certain places of the maxima and minima in time, and of the very slight, almost imperceptible, second minimum which in such cases frequently is found.—In presenting the last report of the Boulder Committee, Mr. Milne Home, the convener, intimated that the Committee purposed giving a general report in a form in which it could be readily compared with the British Association reports. —Mr. W. E. Hoyle read a paper on a new Entozoon from the mesentery of *Proteles cristatus* (Spairman). It is closely allied to *Pentastomum Diesingii* described by Van Beneden, belonging indeed to the same genus, but distinguished by its size, the number of its segments, and a slight difference in shape. The most curious point in its anatomy is that when the animal is encysted in the mesentery of its host the cirrus-sac is empty, and there is a stoppage in the vas deferens. The name proposed for the parasite is *P. Protelis*.

Mathematical Society, June 8.—Mr. J. S. Mackay, F.R.S.E., president, in the chair.—Mr. Thomas Muir, F.R.S.E., communicated some mathematical notes of interest to teachers and a new proof of Prof. Tait's problem of arrangement.—Mr. A. Y. Fraser read a paper on the fundamental notions of the differential calculus; and Dr. C. G. Knott, F.R.S.E., discussed the singularities of plane curves.

Berlin

Physiological Society, May 11.—Prof. Brieger reported on the further results of his study of the violent poisons formed by decomposition of animal bodies. In continuation of the communication he made a short time ago to the Society he described the process by which he had obtained from decomposing masses of flesh a substance which crystallised in acicular forms, and which he obtained by repeated crystallisation in such a degree of purity that he was able to analyse it. It afforded the empirical composition $C_5H_{14}N_2H_2Cl_2$, and consequently was a hydrochloric salt of a new base, which did not in its constitution resemble any known combination. This diamin-base had no longer the toxic properties of the extracts of the decomposition products. It was extremely easily decomposed, and could only be prepared from decomposing meat, and could neither be obtained in the later stages of putrescence nor from decomposing fibrin or other albuminous substances. Neither could it be demonstrated to be a constituent of meat. A second substance was obtained from the mother-liquor that remained after the crystallisation of the diamin-salt. This body, after purification by recrystallisation, showed the composition of $C_5H_{11}NCl$. This base proved to be a very virulent poison; 1 mg. in solution injected subcutaneously into a rabbit very soon produced the set of symptoms characteristic of fish-poison, *i.e.* salivation, quickened respiration, and diarrhœa, followed in a short time by death in convulsions. Even after the isolation of these exceedingly poisonous bases the mother-liquor contained other bases which have as yet not been more closely studied, and which belong to the group denominated by Prof. Brieger, "peptotoxine." They are more or less poisonous in their action upon the living organism, are decomposed with extraordinary facility, and are not only formed in the first stages of decomposition of masses of flesh, but are also contained in neurin in peptones.—Dr. George Hoppe-Seyler, who was present as a visitor, reported the results of the experiments that he made, starting on the basis of the chemical relation of nitrophenylpropiolic acid to indigo, which was studied by Herr Baeyer, in order to determine the physiological action of this acid, hoping thus to advance a step in the comprehension of the formation of indol and oxindol in the living organism. He found that oxindol appeared in the urine of rabbits into whose stomachs he had introduced solutions of nitrophenolpropiolate of soda, the animal in the meantime evincing no morbid symptom. When the solution was subcutaneously injected, blood appeared in the urine along with the oxindol, and when the treatment was continued for some time the constitution of the rabbits was injuriously affected so that they finally died, without, however, manifesting any characteristic symptoms. Dogs behaved quite otherwise when even a third part of that which the rabbits bore without inconvenience was introduced into their stomachs, increasing quantities of albumen and sugar appeared in their urine, and the animals succumbed to emaciation and loss of power. This very remarkable difference in the action of nitrophenylpropiolic acid on dogs and rabbits was not conditioned by the different diet, because when rabbits were driven to take to albuminous diet, by inanition or milk diet, until the reaction of the urine was acid, or when, on the other hand, the urine in dogs was made alkaline by giving them acetate of soda, the differences of the action remained unaltered, and their study promises a key to the comprehension of the origin of albuminuria and glycosuria.

THE LINKS OF THE ANIMAL WORLD

Les Enchaînements du Monde Animal dans les Temps Géologiques. Fossiles Primaires. Par Albert Gaudry, Professeur de Paléontologie au Muséum d'Histoire Naturelle. (Paris : F. Savy, 1883.)

M. GAUDRY, a distinguished palæontologist, contributed five years ago a very interesting volume on the important and much debated question of the mammalia of the Tertiary epoch (see NATURE, vol. xviii. p. 537). The volume which he now publishes relates to the same *quæstio vexata*, but takes into consideration only the fossils that are to be found in primary strata. The author's proposed task is the same in both cases ; he undertakes to find the links and connections that may exist between the animals which have successively or simultaneously inhabited the lands and seas of past epochs.

A great deal has been written on the transformism-theory of Lamarck and Darwin, and it must be expected that much more will be written. One of the principal objections made to it is that if man is really the descendant of the ape, and the ape that of other mammalia, if, generally, there exist links between all animals, living and extinct, so that all animals trace their origin to a common ancestor, how is it that no link really exists between man and ape, or between fish and frog, or between vertebrate and invertebrate? Embryological considerations, it is said, show a real connection between very different animals : a frog for instance is a fish for some time during its youth, and amphioxus looks very much like an ascidian.

But, notwithstanding numerous arguments to support Lamarck's theory, no transformist can show any species gradually losing its peculiar characters to acquire new ones belonging to another species, and thus transforming itself. However similar the dog may be to the wolf, no one has found any dead nor living animal or skeleton which might as well be ascribed to wolf as to dog, and therefore be considered as being the link between the two. One may say exactly as much concerning the extinct species; there is no gradual and imperceptible passage from one to another. Moreover, the first animals that lived on this earth are not, by any means, those that one may consider as inferior and degraded.

M. Gaudry in the first pages of his work states very clearly that he prefers the theory according to which links do exist between the extinct animals of different groups, but he does not show that facts support it yet very strongly.

The opinion one may entertain as to this question being entirely dependent upon facts and the manner of understanding them, let us now turn over the leaves of M. Gaudry's book and see whether we can find in it some firm support to Lamarck's and Darwin's theories.

According to J. Barrande's numerations the number of the species contained in the Silurian strata, comprising the Cambrian, is the following :—

	Species.
Sponges and Protozoa	153
Corals	718
Echinodermata	588
Worms	185
Trilobites	1579
Other Crustaceans	348
Bryozoans	478
Brachiopods	1567
Lamellibranchs	1086
Heteropods and Pteropods	390
Gasteropods...	1316
Cephalopods	1622
Fishes	40
Of uncertain relations	4
	10,074

Thus, in the first of the primary strata nearly all the invertebrates are to be found—excepting insects—and the first vertebrate animals appear.

Generally speaking, and leaving *Eozoon canadense* and *Archæosphærina* out of the question, worms are the oldest fossils to be found in the Silurian strata. It is so in England (Caerfay), in Scandinavia, in France, in Bohemia (Przibram), in America (St. John). In Russia, Crustaceans (Obolus) are the first fossils found. It must be therefore acknowledged that life has not begun on earth with the lowest forms. M. Gaudry, it must also be said, does not believe that such has been the case. M. Gaudry's principal aim is to show that, for instance, all Polyzoa somewhat resemble each other, and that the species are so very similar that the links between them are evident ; but he does not pretend to show the relations between Worms and Crustaceans for instance, and try to find links between them.

M. Gaudry shows easily enough that, according to Nicholson's, Verril's, and Moseley's views, the arrangement and classification of Polyp corals, Zoantharia, Tubipora, Tabulata, and Rugosa is a very difficult thing inasmuch as by some points of their anatomy the species under consideration should come in one group, and by others come in another group. The same thing may be said of Echinoderms.

Between Starfishes and Crinoids there are many links ; others exist between Sea-urchins and Starfish, and Holothurians. As concerns Brachiopods, M. Gaudry remarks that the oldest species of animal on earth is the Lingula, so abundantly found in the Lingula Flags of the English Silurian. It exists to this day, being the best example of "fine old age" yet recorded. Links between the various genera of Brachiopods are not yet very firmly established. Mr. Davidson is opposed to the idea, but Mr. N. Glass's (of Manchester) researches give on the contrary some support to it, by showing how much the arms of the Brachiopods vary and differ in different animals of the same species. Mr. Davidson says that it is often very difficult to ascertain exactly the species of the individuals. Though not having seen, generally speaking, a great number of individuals of the same species, I may say however that of about twenty *Atrypa reticularis* often seen and handled by myself in one of the Parisian geological collections, not two were strictly alike. I have no doubt that the same is true of all, or at least most, species.

Of Mollusks and Crustaceans, M. Gaudry says what he has already said of Brachiopods and other animals. As Dr. Woodward remarks, although Trilobites are always easily distinguishable from other Crustaceans (extinct, of course), one wonders at the astonishing variety afforded by this group of animals.

Let us pass over the Mollusks to see what M. Gaudry says of fishes and other Vertebrates.

Fishes begin in the Upper Silurian strata; they are abundant enough in the Ludlow beds (Pteraspis), and in the Downton grit (bone-bed—Pteraspis, Thelodus, Plectrodus, and Ctenacanthus). The fishes of the first ages of our globe were very singular animals; for instance, *Didymaspis grindrodi* wore on the back a *scutum* very much like that of a queer little Crustacean—at present very abundant in some places around Paris—named *Apus productus*. Pterichthys wore a yet stranger *scutum* which has been ascribed to insects, to Crustaceans, and to turtles before one could understand its meaning; it was incased in a bony helmet, and its fore-fins were also incased in a similar envelope, somewhat like the limbs of a crayfish or a lobster. Those primary fishes were sometimes devoid of a vertebral column, and nothing similar to these animals can be found among the living species. It must be therefore conceded that some links are missing, or that they have not existed.

As to Reptiles, they begin after fishes, in the Carboniferous and Permian strata, at the same time that Batrachia appear. The first of these, *Protriton petrolei*, has been discovered by M. Gaudry in the Permian strata of Autun, in France. *Pleuronoura pellatii*, *Branchiosaurus*, *Apateon*, and many others resemble somewhat the Protriton, and M. Gaudry remarks that these little animals are generally abundant in the same strata where Labyrinthodonts and similar animals are to be found. It may be that some of them are young Labyrinthodonts. Among Reptilia M. Gaudry seems inclined to consider Archegosaurus and Actinodon as the primitive type. They had no real vertebral column, the brain was imperfectly developed, and the limbs were rather imperfect. It is easy to perceive, by careful study of other Reptilia, that they differ from these only very slightly in some cases.

M. Gaudry comes to the following general conclusions:—

There are certainly links between the Silurian, Devonian, Carboniferous, and Permian species, and links exist between these and the actually living species of the same groups. Primary Foraminifera, for instance, are very similar to the actual species of our seas and oceans. This is true also of Brachiopods, Polyps, Mollusks, and Trilobites, but less so of Echinodermata. Brachiopods perhaps llustrate this general theory best, since they are, of all animal groups, the only one that has lasted from the beginning of animal life (Lower Silurian) to the present day.

As d'Omalius d'Halloy says, "It is scarcely credible that the Almighty Being whom I consider as the Author of Nature has, at different times, killed all living animals, to give himself the pleasure of creating new animals, which, very similar to the preceding ones, present successive differences, and display a marked tendency to blend with the actually living forms."

HENRY DE VARIGNY

COLIN CLOUT'S CALENDAR

Colin Clout's Calendar; The Record of a Summer, April-October. By Grant Allen. (London: Chatto and Windus, 1883.)

OF all the writers in this country who seek to render the facts and the theories of modern science attractive to the general public, Mr. Grant Allen is in our opinion among the most successful. We know that he does not profess to be in any serious manner an original investigator of these facts, and we are far from being always ready to accept his theories; but in most of his writings we meet with a characteristic ingenuity of thought, and perhaps a still more characteristic grace of style, which together render his essays the most entertaining in the kind of literature to which they belong.

It has recently been said in these columns, with express reference to Mr. Allen, that this kind of literature does more harm than good to the cause of science and to the advancement of the theory of evolution. But here, we think, the most that can be fairly said is that his zeal may sometimes be in danger of outrunning his discretion, so inducing him to trespass upon the domain of scientific questions which a more technical biologist would feel to be precarious ground. We should remember, however, that the function of a popular writer is to make his material attractive to the general reader, and if he succeeds in doing this for science, we think that he deserves to be encouraged by scientific men, even if they find that in running somewhat too fast over the grounds of theory he occasionally trips over matters of fact. Now, as we have said, Mr. Allen, considered as a literary man, is certainly a man of unusual ability, and he devotes his ability to diffusing an interest in biology among readers of periodical literature, who certainly could not be reached by any less attractive means. Moreover, he is a man of originality, both as regards thinking and observing, and if he were to devote less time to spreading out the sweets of science for popular consumption, there can be little doubt that he might do good work in collecting them.

But, be this as it may, we think that there should be no difference of opinion touching the service which Mr. Allen has rendered in his own province, even if we do not all go so far as to say with Mr. Wallace that he "certainly stands at the head of living writers as a popular exponent of the evolution theory." The book which we have now to notice is restricted to this province, and in its main features resembles those previous volumes which from time to time have been favourably reviewed in these pages. It consists of thirty-nine short papers republished from the *St. James's Gazette*, the greater number of which are devoted to botanical subjects. As the title of the collection suggests, these papers embody a number of observations and reflections on the natural history of plants and animals commonly met with in English country life; and as the essays are written in the least technical and most graphic language, they might be read with profit by all who take any intelligent interest in these things.

We may now give a few quotations, which will serve to show the general nature of the book:—

"But what is most interesting of all about the butterwort is the fact that it is peculiarly adapted for attracting

insects from two distinct points of view—for food, and as fertilisers. While it lays itself out to catch and eat miscellaneous small flies with its gummy leaves, it also lays itself out to allure bees with its comparatively large and handsome mask-shaped flowers. . . . Why should these totally distinct plants [butterwort and sundew], living in precisely similar circumstances, have acquired this curious and uncanny habit of catching and devouring live flies? Clearly, there must be some good reason for the practice: the more so as all other insect-eating plants —Venus's fly-traps, side-saddle flowers, pitcher-plants, bladderworts, and so forth—are invariably denizens of damp watery places, rooting as a rule in moist moss or decaying loose vegetation. Now, in such situations it is difficult or impossible for them to obtain those materials from the soil which are usually supplied by constant relays of animal manure; and under such circumstances, where the roots have no access to decaying animal matter, those plants would flourish best which most utilised every scrap of such matter that happened to fall upon their open leaves."

"The bird which came northward at the close of the glacial period, to inhabit the now thawed plains of northern Europe, much as the American partridge might take possession of Greenland if all its glaciers were to clear away in a more genial era, was doubtless a more or less southern and temperate type of grouse-kind. Coming into Britain, it would soon be entirely isolated from all its allies elsewhere; for it is of course a poor flyer for distance, and it inhabits only the northerly or westerly parts of our island which lie furthest from the Continent, separated from Holland and Scandinavia by a wide sea. Here it could not fail to be subjected to special conditions, differing greatly from those of the European mainland, partly in the equable insular climate, partly in the nature of the vegetation, and partly in the absence of many mammalian foes or competitors. These conditions would be likely first to affect the colouring and marking of the feathers, the spots on the bill, the naked scarlet patch about the eye, and so forth: for we know that even freer-flying birds in the south, which cross often with Continental varieties, tend slightly to vary in such ornamental points; and a very isolated group like the red grouse would be far more likely to vary in similar directions. Meanwhile, the main branch of the family, separated on the great continents from this slightly divergent group, would probably acquire the habit of changing its plumage in winter among the snows of the north, by stress of natural selection, just as the Arctic fox and so many other northern animals have done; for in a uniform white surface any variation of colour is far more certain to be spotted and cut off than in a many-coloured and diversified environment. Thus it would seem probable that the Scotch grouse has slowly become accommodated to the heather, among which it is so hard to discover; while the willow-grouse has grown to resemble the snow in winter, and the barer grounds of its northern feeding-places in the short Scandinavian and Icelandic summer.

"If this be so, we must regard both birds as slightly divergent descendants of a common ancestor, from which, however, our grouse has varied less than its Continental congener. Of course, it is just possible that the common ancestor had already acquired the habit of changing its coat in winter before the divergence took place; and if so, then it is the Scotch grouse which has altered most: but this is less probable, because the usefulness of the change would certainly be felt even in a Scotch winter, and the white suit is not, therefore, likely ever to have been lost when once acquired. Though the winter is not severe enough in Scotland to make such a change of coat inevitable where it does not already exist, it is yet quite severe enough to preserve the habit in animals which have once acquired it, as we see in the case of the varying hare, a creature which in colder ages spread over the whole of northern Europe, and which still holds its own among the chillier portions of the Scotch Highlands. Hence we may reasonably infer that if our grouse had ever possessed a winter coat it would have always retained it for an alternative dress, as the ptarmigan still does in the selfsame latitudes. Accordingly, analogy seems to point to the conclusion that the Scotch grouse is a truly native breed, slightly altered by the conditions of its insular habitat from a closely allied Continental species, whose representatives elsewhere have now all assumed the guise of Scandinavian willow-grouse. In other words, the two isolated groups into which the species has split up have altered each in its own way, but the Continental variety has moved faster away from the primitive type than its British congener."

But in thus recommending Mr. Allen's latest work, we do not wish to appear unduly tolerant of inaccuracy. All we should wish to say is that, assuming Mr. Allen or any other expositor of science to be an amateur not thoroughly versed in technical matters, and therefore liable to fall into technical errors, we do not feel on this account that he need be precluded from publishing his observations and his theories for whatever they may be worth. Sooner or later these are sure to be duly winnowed, and even though they may contain more chaff than Mr. Allen has been in the habit of presenting, they may also contain some seeds of germinative value.

GEORGE J. ROMANES

AGRICULTURE IN INDIA

Field and Garden Crops of the North-Western Provinces and Oudh. Part I. With illustrations. By J. F. Duthie, B.A., Superintendent of the Saharanpur Botanical Gardens, and J. B. Fuller, Assistant Director of Agriculture and Commerce, North-West Provinces and Oudh. (Printed at the Thomason Civil Engineering College Press, 1882.)

THIS *brochure* is the first of a short series in which it is proposed to describe the cultivated products of the North-West Provinces of India. With the exception of an introduction of considerable length, treating generally of the physical, social, and agricultural peculiarities of the North-Western Provinces, the volume is chiefly devoted to a description of farm crops. Many of these, such as wheat, barley, oats, maize, hemp, tobacco, millet, and poppy, are as familiar to European cultivators as to Asiatics. Others, such as opium, rice, sugar-cane, and cotton, betoken the tropical nature of at least a portion of the season. The botanical descriptions of the various crops are contributed by Mr. Duthie in the usual language of the text-books, affording little room for original remark of any kind. By far the greater portion of the work has been compiled from the reports of Settlement Officers and other Government records, or contributed by Mr. Fuller. The agricultural information is of a highly interesting character, and the illustrations are particularly excellent. The work is, however, in a manner disfigured and rendered obscure by the peculiar views of the authors as to the first rule of arithmetic. Sixty-seven millions, &c., are expressed as 6,79,06,496, and six millions, &c., as 64,96,567. Ten millions, &c., are written in figures as 1,09,57,837. This principle of notation renders the statistical portion of the work difficult to follow, and it is not easy to see why it has been adopted.

The text is not free from remarks betokening a want of knowledge as to the progress of research on certain points. When, for example, treating of the enemies which affect the wheat crop, the author (presumably Mr. Fuller) writes as follows:—"But by far the most extraordinary disease to which wheat is liable is *schwan*, in which the young wheat-grains are found to be filled with minute worms . . . The most extraordinary fact connected with this disease is, however, that the worms can retain their vitality for a long time," &c. A footnote is then added as follows:—"Since the above was written, the worms have been identified as belonging to the order *Nematoidea*, and are apparently of the genus *Tylenchus*"! This is really too gross and wilful ignorance. The well-known and often-described "pepper brand" or "ear-cockle" attributable to the *Vibrio tritici*, now known as the *Tylenchus tritici*, is paraded as a "most extraordinary" disease, the precise nature of which has been ascertained "since the above was written." If such is the fact, the figures 1882 should be withdrawn from the title-page, and 1828 be substituted in their place. Neither do the authors appear to be at home in treating of the varieties of the cultivated plants. The varieties of rice, we are told, are more numerous and more strongly marked than those of any other crop. Forty-seven distinct varieties are announced, in support of this statement, as existing in Bareilly, although the writer proceeds somewhat naïvely to add, "Probably in the Provinces their number considerably exceeds 100." Now, as 300 varieties of wheat have been propagated by one naturalist, the forty-seven varieties of rice do not strike us as bearing out the statement as to the extraordinary variability of the plant.

Another point we cannot forbear to notice is the evident carelessness on the part of the authors as to whether their work should be understood by Englishmen in England. What is a "lakh," a "maund," or a "seer"? In vain we look for an English equivalent, and yet it is "maunds" *per acre* which are constantly spoken of, and which we long to translate into bushels or some intelligible unit of measure or weight. Viewing the volume as a whole, we cannot but pronounce it interesting and readable. The introduction is especially rich in information regarding the climate, irrigation, and cultivation of the North-West Provinces, a vast district comprising, in the quaint method of enumerating employed by the authors, 6,79,06,496 acres.

An alluvial soil and a climate by which the year is divided into two complete seasons certainly are conditions highly favourable to vegetation and to agriculture. In the colder season, wheat, barley, and oats are brought to perfection, while in the kharif, or hot season, rice, cotton, sugar-cane, and maize thrive. Not only do these highly-favoured provinces enjoy a temperate and a tropical climate, but each half of the year is again divided into two definite sub-seasons fitted for producing crops peculiar to it. We cannot but wonder whether the strange climatal vagaries to which the western world has latterly been exposed have disturbed the pleasant division of the year into kharif and rati in the North-West Provinces of India; but on this point our authors are silent.

Auroræ of October 2 and November 17, 1882

THE article of Mr. Rand Capron in the *Philosophical Magazine* on the aurora of November 17, 1882, has proved to me that my observation of that phenomenon has not been without value, but it appears that Mr. Capron has been obliged to consult a not quite accurate abstract or translation of my description which I had inserted in the *Utrecht Journal*; it was from lack of time that I did not immediately send translations of it to foreign periodicals.

Perhaps you will still be so kind as to admit into NATURE a translation of both my articles on the auroræ of October 2 and of November 17; they were written immediately after observing the phenomenon. J. A. C. OUDEMANS

Utrecht, June 9

Translation of the Article in the "Utrecht Journal" of October 3, 1882

Yesterday evening, between seven and eight o'clock, there appeared here a brilliant aurora. Before seven there was visible a white arc running from west to east. This arc grew clearer and clearer, and rose slowly, till at 7h. 5m. (mean time) there emanated brilliant beams from its whole circumference.

At 7h. 10m. there rose also a bright column from the east-north-east, which phenomenon was repeated now and then also from the west.

In the southern part of the sky a magnificent sight was the large white spots, looking like brightly illuminated white clouds, but proving by their variable brilliancy to be no clouds, but to be connected with the auroral light. At 7h. 15m. such a large white spot was just before Aquila, *i.e.* north of the equator, but the spots showed a movement to the south, so that at 7h. 30m. the zone formed by them was some degrees south of the equator.

At 7h. 42m. there arose a large beam through the quadrangle of Ursa Major to β Ursa Minoris; this beam moved to the west, and was dissolved a few minutes afterwards.

At 7h. 50m. there appeared again a cloudy patch in Aquila.

At 7h. 54m. a brilliant shooting star descended almost vertically from the space between Lyra and the Dragon through Hercules; this observation was, however, not made with accuracy.

At 8h. the last cloudy patches in the south vanished; in the north also I saw no more upward radiating beams.

Long afterwards the auroral light remained visible in the north. After 8h. 30m. I did not longer look for the phenomenon; it seemed to me to have come to an end.

Utrecht, October 3, 1882 J. A. C. O.

Translation of the Article in the "Utrecht Journal" of November 18, 1882

Yesterday we had again a brilliant aurora, differing entirely in its details from that of October 2.

In the east as well as in the west there appeared at 6h. mean time a red gleam like that of a distant fire. Both these extended red patches were united through the north by an arc much resembling that which appeared in the aurora of October 2. The splendid vertical beams remarked on that occasion were now fewer in number and not so intense; they were of the same reddish hue as the above-mentioned patches visible in the east and in the west.

At 6h. 23m. there appeared suddenly in the east a bright featherlike[1] appearance, which in the beginning showed some resemblance to a comet; the end of it was exactly above Aldebaran. In no more than two minutes this feather had lengthened over an arc that passed above Saturn, through the quadrangle of Pegasus, and south of the Aquila stars, and as the front or western end proceeded, the eastern end followed. With the aid of a star-map we see that the arc, covered successively by this featherlike appearance, was elevated 20° above the

[1] By this word I did not mean that the borders or edges were not fairly defined.

celestial equator, and that its intersections with that equator had R.A. 110° and 290°. The horizon was intersected by this arc about 18° N. of E. and 18° S. of W., *i.e.* in two points situated nearly 90° from the magnetic meridian (Mr. R. Capron cites 20° erroneously; a repeated calculation gives me 18° 14′ N. of E).

When the arc was visible over more than 90° (which lasted no longer than a few seconds), its middle part, having a breadth of about 3°, was separated by a dark rift, 10° long and ½° broad, sharp at both ends.

At 6h. 25m the whole arc had vanished.

At 6h. 27m. a bundle of red rays appeared between Ursa Major and Ursa Minor; it extended from Polaris to γ Ursæ Minoris, *i.e.* over a width of almost 20 degrees; this bundle moved steadily to the west, just as had been the case with several vertical beams of the former aurora.

At 6h. 30m. clouds began to appear in different parts of the sky: first in Auriga, in the E.N.E.; a moment afterwards another in Aries. In the beginning it was not evident if they were clouds or auroral phenomena, but they proved soon to be clouds floating off southwards by the north wind.

The aurora had now lost much of its splendour; I noted still a few beams, viz.:—

At 6h. 32·5m. a beam about 10° east of Polaris; at 6h. 33m. the red beam, discovered at 6h. 27m., had so far shifted to the west that it went through the head of the Dragon; at 6h. 37m. there was still a faint beam extending from α Coronæ (visible in the twilight) to Vega, which stood higher and more to the south.

At 6h. 38m. there was a white band between α Aurigæ and α Persei; I was not sure if it was auroral or a cloud.

At 6h. 40m. there appeared two new very broad beams in the north-west.

Now the east becomes more and more covered; from the north to the west there extends itself a whitish glow to a height of 40 degrees; in the north-east this glow is much feebler and lower; therefore I estimate it as not higher than from 20 to 30 degrees. It flows off very indistinctly. The polar light seemed now to have passed its greatest intensity; the observations were no longer continued.

A part of the night a white auroral light remained still visible over the northern sky; at 9h. the sky was entirely overcast.

At midnight it was clear again, and the whole northern sky was always covered by an auroral light; I am told that it was still there at 5h. in the morning.

It is said to have been then in the north-west, of a purple colour, in the north-east more pale yellow. J. A. C. O.

Utrecht, November 18, 1882

Effects of Lightning

PERHAPS your readers will be interested in the following remarkable incident of the action of lightning which has just occurred at the village of Great Lumley, near Chester-le-Street, in Durham.

A severe thunderstorm passed over the valley of the Wear on Saturday, June 9. Great Lumley is situated on the top of an elevated plateau on the east side of this valley, and its houses are conspicuously exposed to the weather. At about 11 a.m., during the progress of the storm, an old stone house with steep pantiled roof, known as the "Old Hall," was struck by a thunderbolt. The house is only of moderate height, having three low stories; but it is on some of the highest ground in the village, and is also one of the loftiest houses therein. It is on the south side of the principal street forming the village, and it has two gable ends, which are, however, partially concealed at their lower portions by lower houses joining on. There is a yard in rear of the "Old Hall," separating it by a few yards from some smaller houses mostly inhabited by pitmen. The coal lies about seventeen fathoms below the surface, and there are several pits in the neighbourhood.

The principal damage done to the house is in the internal woodwork; but a hole has also been made in the tiled roof, the upper courses of a brick chimney-stack built over the centre of a brick partition wall which divides the building into two separate dwelling-houses have been thrown down, and some broken bricks and tiles were hurled as far as sixty feet distant to the southward. The building is about 220 years old, and is externally in a rather dilapidated condition. The masonry is rough sandstone rubble, the surface of which has in places been much disintegrated by age and weather. The building is Lord Durham's property, and is let in tenements. At the time of the accident the whole of its eastern dwelling-house was unfurnished and uninhabited. This was where the principal injuries were effected. The western compartment is occupied; and the inmates were knocked down by the concussion, various pieces of furniture being also damaged by the same cause; but nothing serious occurred. The building, being so old, has also experienced considerable damage externally from the tremendous concussion which appears to have accompanied the explosion of the thunderbolt. Loose tiles and stones have been dislodged; an old wooden frame in a window-opening in the loft at the east gable has been thrown to the ground below, and a considerable patch of surface masonry immediately above the window-opening has been shaken down. Falling bricks and stones have also made some holes in adjoining roofs; and the signs of injury shown by all these causes led the people in the adjacent houses to believe that these damages constituted the extent of the harm done by the explosion. I inspected the scene just three days after the event. The eastern and unused portion of the "Old Hall" had not then been examined internally, and the doors were still locked.

On visiting the interior I found that great injury had been done to a wooden rafter of the roof, close to the hole already mentioned; to a wooden upright post resting on the second floor and supporting this rafter; and to a wooden girder and joist sustaining the foot of the post. The plaster on the walls adjacent to the post and girder was also torn off; but below the first floor no certain trace of the explosion could be found. The damaged rafter is on the south side of the roof, and the nearest one on the east of the chimney. Its scantling is 6 inches broad by 3 inches deep; and at about one-third of its length from the eaves it is supported by a longitudinal purlin (on a level with the floor of the loft), and also (just inside the purlin) by the upright post already mentioned. From the level of the upper side of the purlin, for a length of about 6 feet upwards, the rafter is completely shivered, and two large pieces are torn out of it. One, the lower piece, is 3 feet 6 inches long, 3 inches wide, and about 1½ inch deep. This has been cut very neatly out of the west side of the under face of the rafter, leaving the new under face almost smooth; and the lower end of the scar thus formed is scooped out in a *dovetailed* form flush with the horizontal top of the adjacent purlin. No broken pieces corresponding to this scar could be found anywhere about the small loft; but some very small splinters of wood were discovered on the floor to the north-east of the rent rafter and in the direction of the window-opening already mentioned. This latter was quite open to the outer air when the accident happened, and immediately after it occurred numerous small splinters of wood were found in the yard to the eastward of the opening. These had evidently been blown out of it with the old window frame. Some were found against a low wall horizontally distant 63 feet from the opening. These splinters were not visible when I arrived, as they had at once been secured for firewood by the spectators; but I brought away one of the fragments found on the loft floor. Its fibres are quite disevered from each other, as if the wood had been completely *permeated* along their direction by the force of the explosion. The other scar in the rafter is cut out of the under face on the east side, partly alongside the first scar, but extending higher up and ending just under the hole in the roof tiles already mentioned. This second scar is 3 feet long by 4 inches by about 2 inches, and two pieces of wood were found lying on the loft floor about 8 feet distant to the north-east, which exactly fitted this scar. The hole through the roof is made at a point where a small iron nail fixed a lath (for the tiles) to the rafter.

The upright post underneath the rafter has a scantling of 8 inches by 3 inches; it is split and torn right up from its foot at the second floor (the next floor below the loft) to its junction with the rafter, to which it was fixed by several 2½-inch iron nails. The exact joint between the principal splits in the post and rafter seemed to be at the position of one of these nails, which was almost laid bare. I brought this nail away. Its upper two-thirds is quite rusty, whilst its lowest third (nearest the point) is clean and, in minute places, nearly bright. A heavy piece measuring 7 feet 6 inches by 6 inches by about 3 inches was torn clean off the north-west angle of this upright, and was found lying on the second floor about 3 feet off to the northward. The upright forms an angle post on the east side of a sort of dormer or porch projecting out of the south side of the roof, and formerly giving access from the outside to the second floor by a step-ladder. The latter, however, had disappeared shortly

before the accident occurred, having (as I understood) fallen down from age. The upright is split vertically in two places, one (where the piece was rent off) following exactly the line of the small iron nails which fixed the laths (for the wall plaster) to the upright, and the other about 2 inches to the east of this line. At this east split the outer portion of the upright is forced outwards about 4 inches from the centre portion, and all but separated from it. Along the line of the first split the lath nails are forced out of the upright, and the lath ends pushed outwards, and some broken off. A great patch of the plaster that covered them (the centre of it being about 4 feet above the floor) is torn off and thrown violently against the north wall of the building on the opposite side of the room 21 feet distant. The wall is dotted (high and low) with white powdery marks, and the floor at the foot of it is covered with broken and powdered plaster, as also is (more or less) the space of intervening floor. The splits in the upright unite upwards, and pass through the loft floor at a comparatively small orifice, and the piece rent out tapers considerably from the bottom upwards. The rent surface of this piece is minutely *fretted* in a curious manner. In the bottom of the rent off piece (which comprised the greater part of the sectional area of the post at this end) were three or four $2\frac{1}{2}$-inch iron nails, probably used for fixing the post to the floor. These appeared to be driven and bent into the wood; there was no sign of fusing on them, and the surface of the floor immediately underneath the bottom of the post was not in the slightest degree damaged, so far as could be detected. On each side of the slight brickwork forming the east wall of the dormer or porch, a small patch of plaster (about 6 inches square or so) was broken off close to the floor, and about 3 feet southward of the post, but no other marks attributable to the explosion (and these small patches might have been due only to the concussion) could be discovered at the second floor.

On entering the room below (on the first floor), which has no ceiling, it was found that the wooden girder ($9\frac{1}{2} \times 4\frac{1}{2}$), on which the post rested, had a splinter 16 inches long and about 1 inch square (on an average) torn horizontally off the east side of it, 3 or 4 feet to the southward of the position of the bottom of the post, and about 6 feet from the south wall. The girder extends across the room, and rests on the north and south walls. Below the splinter, on the same girder, there was a horizontal crack, extending through the breadth of the girder, and proceeding about 8 feet along it northward, but stopping short of the position of the post above. It seemed, however, *possible* that there might be yet another horizontal split in this girder *close* to the under side of the floor above, and extending right up to the position of the post. Along the west side of the girder is a short joist (7 inches by 3 inches) passing through the south wall, extending about 4 feet into the room, and fixed to the girder by three large iron trenails; and just below it there was some more slight woodwork bedded in the wall, and apparently rotten. This joist was forced out from the other about 1 inch, and had a horizontal split passing exactly along the line of the heads of the three trenails, and completely separating it into two layers. A small piece of the rotten wood underneath (about 6 inches by 2 inches by $\frac{1}{2}$ inch) was broken off, and thrown about 4 feet into the room on the floor to the north. An irregular patch of damp plaster about 4 feet by 18 inches, which had formerly concealed this rotten woodwork, was torn off, and most of it was (as in the room above) thrown hard against the opposite north wall, to which portions were still adhering. These portions are chiefly high up the wall, and near the floor above. Some larger pieces were also spread over the intervening space. The wall where this plaster was torn off was almost saturated with moisture, and the plaster round the rent piece was quite wet and discoloured.

There are no certain traces of the thunderbolt visible on the outside of the south wall, where, however, it most assuredly must have been present. The ground at the foot showed no signs of rending. There was a small lean-to outhouse nearly below, the roof of which was damaged; but I was led to understand that this had been done before; and as the place was locked, and my time was limited, I did not go inside it. At the angle made by one of the side walls of this outhouse with the main building, and not far from a point vertically below the position of the end of the girder, was a wet piece of ground habitually used for emptying slops at; and this seemed by no means an unlikely place for the thunderbolt to have originated. Here and there on the face of the dilapidated masonry some rather new looking abrasions were to be seen; but not even just abreast of the end of the girder could I detect for certain any traces of the explosion; and no metal of any kind was visible. In this connection it may be mentioned that there were no eaves-gutters, rain-water pipes, or metals of any sort on the outside of the house or on the roof.

Perhaps the most noteworthy feature of this accident was the *complete absence of any sign of burning or charring* at the rents in the girder, joist, post, and rafter. The nails struck also showed no symptoms of fusing; and, for all the *traces* that were left by the stroke, it might have been quite unaccompanied by heat. The work of the explosion seems to have taken altogether the form of mechanical violence. The wood of the post, rafter, and girder is sound, dry, old fir, and this would seem peculiarly liable to be set on fire.

The almost perpendicular bend that the course of the stroke seems to have taken from the girder to the post is also very curious. That the direction and force of the stroke was *upward* appears to me a conclusion quite irresistible. I have but little doubt in my own mind, from the traces left by the thunderbolt, that it sprang from the ground outside the building, at or near the wet south wall; passed up its outer face, entered the building through the wall at the rotten wood, and passed through or close to the joist and girder; then, attracted by the nails in the bottom of the post, it took a sudden turn upward (for there were no other marks of its course in the first floor room than those described), cleft right through the heart of the post, altered its course obliquely to gouge out the lower part of the rafter as far as the small nail, broke through the tiles, knocked off the chimney-top, and thence rushed to join the complementary force that had already started from the thundercloud to meet it. The Soaring of Birds

IN NATURE, vol. xxvii. p. 535, Lord Rayleigh gives what he suggests as a possible explanation of the soaring of "pelicans and other large birds in Assam" mentioned by Mr. S. E. Peal. My own observations correspond so exactly with the theory advanced that I venture to give them for whatever they may be worth.

I have never indeed observed the flight of pelicans, but the Indian kite, the turkey buzzard, and perhaps all vultures, have the same habit of soaring in great circles. The *sandhill crane*, as it is commonly called in the United States, a large migratory crane, possesses this characteristic in a most remarkable degree. These birds will go soaring about for hours at an immense height, never seeming to move a pinion except once in a great while to steady themselves a little. They always move in irregular circles at such times, and there is always a drifting with the wind; but at such a great distance above one it would be impossible by mere ordinary observation to detect the obliquity of the circles if it existed.

A short time since, however, I had a fine opportunity of witnessing the soaring of some kites; the advantageous circumstances being that they were not far away, and that I saw them commence when they were so low that there was little chance of being mistaken in what I saw. I was sitting before an open window one day about eleven o'clock. There was a gentle breeze blowing from the south-east at the time. Presently my attention was attracted by several kites over the village to the north-west. The motions of two in particular I followed for some time. After moving their wings to attain an elevation above the houses and trees they began soaring, and continued upward in this manner to a height of perhaps two thousand feet, apparently making no exertion with their wings excep to steady themselves a little occasionally. The method of accomplishing this was evidently to circle away to leeward in a great curve which inclined downward a little, thus acquiring considerable momentum; then turning toward the wind and adjusting the surfaces of the wings to the proper angle, they would shoot upward to a point considerably higher than the one from which the circle began. By the time the momentum was exhausted the bird was circling around again for another sweep to leeward.

There was considerable drifting with the wind, so that in attaining an elevation of some two or three thousand feet the birds had moved away nearly a quarter of a mile. Their consequent upward motion was in an irregular spiral, the highest parts of the curves being on the windward side.

Ongole, India, May 21 W. R. MANLEY

Geology of Cephalonia

IN answer to the inquiry of your correspondent in the last number of NATURE (p. 173) I beg to inform him that the shells of the Pliocene formation in the Morea have been long since investigated, as is shown by the great and well-known work of Hörnes. And Dr. Fischer has published a list of the fossil shells from the same formation at Rhodes. These subapennine beds extend over the whole of the south of Europe. For many of those species which are still living I have given the localities of the Morea and Rhodes as fossil in the *Proceedings of the Zoological Society*.

On the Chemical Characters of the Venom of Serpents

DR. WEIR MITCHELL calls my attention to an error in the brief notice which I wrote in NATURE recently (vol. xxviii. p. 114), on the researches into the chemical characters of snake poison conducted by him and Dr. Reichart. It is that instead of "They are unable to confirm the statement of Gautier of Paris that an alkaloid resembling a ptomaine exists in cobra poison; *or that of Prof. Wolcott Gibbs, that the poison of Crotalus yields an alkaloid*," it should be, "Prof. Wolcott Gibbs was unable to find an alkaloid."

Earthquake in South-West England

I HAVE just felt and heard the shock of an earthquake. The trembling of the earth was very great and the accompanying noise very loud, comparing it with one or two other slight shocks which I have before experienced in this district. I found the time to be 1.38 p.m. The time it lasted was several seconds. It was longer and louder than an ordinary clap of thunder when the lightning is not far off. A man reports that the slates of the cow-house were made to rattle.

As I now write (2.7 p.m.) a second shock has been felt, a little less severe. The weather is very calm, sky cloudy. This place is close to Dartmoor, on the westward side, about 500 feet above the sea-level.

W. F. COLLIER

Woodtown, Horrabridge, S. Devon, June 25

I BEG to inform you of the occurrence of two slight earthquake shocks here to-day, one shortly before 2 p.m., the other near half an hour later. The direction of progress seemed to be from north-west to south-east—that is along the line of the deep and narrow valley. The tremor was sufficient to cause jangling of glass and earthenware, and of the slates covering the house. The usual rumbling noise accompanied the shocks.

ON WHALES, PAST AND PRESENT, AND THEIR PROBABLE ORIGIN[1]

FEW natural groups present so many remarkable, very obvious, and easily appreciated illustrations of several of the most important general laws which appear to have determined the structure of animal bodies, as those selected for my lecture this evening. We shall find the effects of the two opposing forces—that of heredity or conformation to ancestral characters, and that of adaptation to changed environment, whether brought about by the method of natural selection or otherwise—distinctly written in almost every part of their structure. Scarcely anywhere in the animal kingdom do we see so many cases of the persistence of rudimentary and apparently useless organs, those marvellous and suggestive phenomena which at one time seemed hopeless enigmas, causing despair to those who tried to unravel their meaning, looked upon as mere will-of-the-wisps, but now eagerly welcomed as beacons of true light, casting illuminating beams upon the dark and otherwise impenetrable paths through which the organism has travelled on its way to reach the goal of its present condition of existence.

[1] Lecture delivered at the Royal Institution on the evening of Friday, May 25, 1883, by Prof. Flower, LL.D., F.R.S., P.Z.S., &c.

It is chiefly to these rudimentary organs of the Cetacea and to what we may learn from them that I propose to call your attention. In each case the question may well be asked, granted that they are, as they appear to be, useless, or nearly so, to their present possessors, insignificant, imperfect, in fact *rudimentary*, as compared with the corresponding or homologous parts of other animals, are they survivals, remnants of a past condition, become useless owing to change of circumstances and environment, and undergoing the process of gradual degeneration, preparatory to their final removal from an organism to which they are only, in however small a degree, an incumbrance, or are they incipient structures, beginnings of what may in future become functional and important parts of the economy? These questions will call for an attempt at least at solution in each case as we proceed.

Before entering upon details, it will be necessary to give some general idea of the position, limits, and principal modifications of the group of animals from which the special illustrations will be drawn. The term "whale" is commonly but vaguely applied to all the larger and middle-sized Cetacea, and though such smaller species as the dolphins and porpoises are not usually spoken of as whales, they may to all intents and purposes of zoological science be included in the term, and will come within the range of the present subject. Taken all together the *Cetacea* constitute a perfectly distinct and natural order of mammals, characterised by their purely aquatic mode of life and external fishlike form. The body is fusiform, passing anteriorly into the head without any distinct constriction or neck, and posteriorly tapering off gradually towards the extremity of the tail, which is provided with a pair of lateral pointed expansions of skin supported by dense fibrous tissue, called "flukes," forming together a horizontally-placed, triangular propelling organ. The forelimbs are reduced to the condition of flattened ovoid paddles, incased in a continuous integument, showing no external sign of division into arm, forearm, and hand, or of separate digits, and without any trace of nails. There are no vestiges of hind-limbs visible externally. The general surface of the body is smooth and glistening, and devoid of hair. In nearly all species a compressed median dorsal fin is present. The nostrils open separately or by a single crescentic valvular aperture, not at the extremity of the snout, but near the vertex.

Animals of the order *Cetacea* abound in all known seas, and some species are inhabitants of the larger rivers of South America and Asia. Their organisation necessitates their life being passed entirely in the water, as on the land they are absolutely helpless; but they have to rise very frequently to the surface for the purpose of respiration. They are all predaceous, subsisting on living animal food of some kind. One genus alone (*Orca*) eats other warm-blooded animals, as seals and even members of its own order, both large and small. Some feed on fish, others on small floating crustacea, pteropods, and medusæ, while the staple food of many is constituted of the various species of Cephalopods, chiefly *Loligo* and other *Teuthidæ*, which must abound in some seas in vast numbers, as they form almost the entire support of some of the largest members of the order. With some exceptions the Cetacea generally are timid, inoffensive animals, active in their movements, sociable and gregarious in their habits.

Among the existing members of the order there are two very distinct types—the Toothed Whales, or *Odontoceti*, and the Baleen Whales, or *Mystacoceti*, which present throughout their organisation most markedly distinct structural characters, and have in the existing state of nature no transitional forms. The extinct *Zeuglodon*, so far as its characters are known, does not fall into either of these groups as now constituted, but is in some respects intermediate, and in others more resembles the generalised mammalian type.

The important and interesting problem of the origin of the Cetacea and their relations to other forms of life is at present involved in the greatest obscurity. They present no more signs of affinity with any of the lower classes of vertebrated animals than do many of the members of their own class. Indeed in all that essentially distinguishes a mammal from one of the oviparous vertebrates, whether in the osseous, nervous, vascular, or reproductive systems, they are as truly mammalian as any, even the highest, members of the class. Any supposed signs of inferiority are, as we shall see, simply modifications in adaptation to their peculiar mode of life. Similar modifications are met with in another quite distinct group of mammalia, the *Sirenia*, and also, though in a less complete degree, in the aquatic Carnivora or seals. But these do not indicate any community of origin between these groups and the Cetacea. In fact, in the present state of our knowledge, the Cetacea are absolutely isolated, and little satisfactory reason has ever been given for deriving them from any one of the existing divisions of the class more than from any other. The question has indeed often been mooted whether they have been derived from land mammals at all, or whether they may not be the survivors of a primitive aquatic form which was the ancestor not only of the whales, but of all the other members of the class. The materials for—I will not say solving—but for throwing some light upon this problem, must be sought for in two regions—in the structure of the existing members of the order, and in its past history, as revealed by the discovery of fossil remains In the present state of science it is chiefly on the former that we have to rely, and this therefore will first occupy our attention.

One of the most obvious external characteristics by which the mammalia are distinguished from other classes of vertebrates is the more or less complete clothing of the surface by the peculiar modification of epidermic tissue called hair. The Cetacea alone appear to be exceptions to this generalisation. Their smooth, glistening exterior is, in the greater number of species, at all events in adult life, absolutely bare, though the want of a hairy covering is compensated for functionally by peculiar modifications of the structure of the skin itself, the epidermis being greatly thickened, and a remarkable layer of dense fat closely incorporated with the tissue of the derm or true skin; modifications admirably adapted for retaining the warmth of the body, without any roughness of surface which might occasion friction and so interfere with perfect facility of gliding through the water. Close examination, however, shows that the mammalian character of hairiness is not entirely wanting in the Cetacea, although it is reduced to a most rudimentary and apparently functionless condition. Scattered, small, and generally delicate hairs have been detected in many species, both of the toothed and of the whalebone whales, but never in any situation but on the face, either in a row along the upper lip, around the blowholes or on the chin, apparently representing the large, stiff "vibrissæ" or "whiskers" found in corresponding situations in many land mammals. In some cases these seem to persist throughout the life of the animal; more often they are only found in the young or even the fœtal state. In some species they have not been detected at any age.

Eschricht and Reinhardt counted in a new born Greenland Right Whale (*Balæna mysticetus*) sixty-six hairs near the extremity of the upper jaw, and about fifty on each side of the lower lip, as well as a few around the blowholes, where they have also been seen in *Megaptera longimana* and *Balænoptera rostrata*. In a large Rorqual (*Balænoptera musculus*), quite adult and sixty-seven feet in length, stranded in Pevensey Bay in 1865, there were twenty-five white, straight, stiff hairs about half an inch in length, scattered somewhat irregularly on each side of the vertical ridge in which the chin terminated, extending over a space of nine inches in height and two and a half inches in breadth. The existence of these rudimentary hairs must have some significance beyond any possible utility they may be to the animal Perhaps some better explanation may ultimately be found for them, but it must be admitted that they are extremely suggestive that we have here a case of heredity or conformation to a type of ancestor with a full hairy clothing, just on the point of yielding to complete adaptation to the conditions in which whales now dwell.

In the organs of the senses the Cetacea exhibit some remarkable adaptive modifications of structures essentially formed on the Mammalian type, and not on that characteristic of the truly aquatic Vertebrates, the fishes, which, if function were the only factor in the production of structure, they might be supposed to resemble.

The modifications of the organs of sight do not so much affect the eyeball as the accessory apparatus. To an animal whose surface is always bathed with fluid, the complex arrangement which mammals generally possess for keeping the surface of the transparent cornea moist and protected, the movable lids, the nictitating membrane, the lacrymal gland, and the arrangements for collecting and removing the superfluous tears when they have served their function cannot be needed, and hence we find these parts in a most rudimentary condition or altogether absent. In the same way the organ of hearing in its essential structure is entirely mammalian, having not only the sacculi and semicircular canals common to all but the lowest vertebrates, but the cochlea, and tympanic cavity with its ossicles and membrane, all, however, buried deep in the solid substance of the head; while the parts specially belonging to terrestrial mammals, those which collect the vibrations of the sound travelling through air, the pinna and the tube which conveys it to the sentient structures within are entirely or practically wanting. Of the pinna or external ear there is no trace. The meatus auditorius is certainly there, reduced to a minute aperture in the skin like a hole made by the prick of a pin, and leading to a tube so fine and long that it cannot be a passage for either air or water, and therefore can have no appreciable function in connection with the organ of hearing, and must be classed with the other numerous rudimentary structures that whales exhibit.

The organ of smell, when it exists, offers still more remarkable evidence of the origin of the Cetacea. In fishes this organ is specially adapted for the perception of odorous substances permeating the water; the terminations of the olfactory nerves are spread over a cavity near the front part of the nose, to which the fluid in which the animals swim has free access, although it is quite unconnected with the respiratory passages. Mammals, on the other hand, smell substances with which the atmosphere they breathe is impregnated; their olfactory nerve is distributed over the more or less complex foldings of the lining of a cavity placed in the head, in immediate relation to the passages through which air is continually driven to and fro on its way to the lungs in respiration, and therefore in a most favourable position for receiving impressions from substances floating in that air. The whalebone whales have an organ of smell exactly on the mammalian type, but in a rudimentray condition. The perception of odorous substances diffused in the air, upon which many land mammals depend so much for obtaining their food, or for protection from danger, can be of little importance to them. In the more completely modified Odontocetes the olfactory apparatus, as well as that part of the brain specially related to the function of smell is entirely wanting, but in both groups there is not the slightest trace of the specially aquatic olfactory organ of fishes. Its complete absence and the vestiges of the aërial organ of land mammals found in the Mystacocetes are the clearest possible indications of the origin of the Cetacea from air-breathing and air-smelling terrestrial

mammalia. With their adaptation to an aquatic mode of existence, organs fitted only for smelling in air became useless, and so have dwindled or completely disappeared. Time and circumstances have not permitted the acquisition of anything analogous to the special aquatic smelling apparatus of fishes, the result being that whales are practically deprived of whatever advantage this sense may be to other animals.

It is characteristic of the greater number of mammalia to have their jaws furnished with teeth having a definite structure and mode of development. In all the most typical forms these teeth are limited in number, not exceeding eleven on each side of each jaw, or forty-four in all, and are differentiated in shape in different parts of the series, being more simple in front, broader and more complex behind. Such a dentition is described as "heterodont." In most cases also there are two distinct sets of teeth during the lifetime of the animal, constituting a condition technically called "diphyodont."

All the Cetacea present some traces of teeth, which in structure and mode of development resemble those of mammals, and not those of the lower vertebrated classes, but they are always found in a more or less imperfect state. In the first place, at all events in existing species, they are never truly heterodont, all the teeth of the series resembling each other more or less or belonging to the condition called "homodont," and not obeying the usual numerical rule, often falling short of, but in many cases greatly exceeding it. The most typical Odontocetes, or toothed whales, have a large number of similar, simple, conical, recurved, pointed teeth, alike on both sides and in the upper and under jaws, admirably adapted for catching slippery, living prey, such as fish, which are swallowed whole without mastication. In one genus (*Pontoporia*) there may be as many as sixty of such teeth on each side of each jaw, making 240 in all. The more usual number is from twenty to thirty. These teeth are never changed, being "monophyodont" and they are, moreover, less firmly implanted in the jaws than in land mammals, having never more than one root, which is set in an alveolar socket which is generally wide and loosely fitting, though perfectly sufficient for the simple purpose which the teeth have to serve.

Most singular modifications of this condition of dentition are met with in different genera of toothed whales, chiefly the result of suppression, sometimes of suppression of the greater number, combined with excessive development of a single pair. In one large group, the Ziphioids, although minute rudimentary teeth are occasionally found in young individuals, and sometimes throughout life, in both jaws, in the adults the upper teeth are usually entirely absent, and those of the lower jaw reduced to two, which may be very large and projecting like tusks from the mouth, as in *Mesoplodon*, or minute and entirely concealed beneath the gums, as in *Hyperoodon*,—an animal which is for all practical purposes toothless, yet in which a pair of perfectly formed though buried teeth remain throughout life, wonderful examples of the persistence of rudimentary and to all appearance absolutely useless organs. Among the *Delphinidæ* similar cases are met with. In the genus *Grampus* the teeth are entirely absent in the upper, and few and early deciduous in the lower jaw. But the Narwhal exceeds all other Cetaceans, perhaps all other vertebrated animals, in the specialisation of its dentition. Besides some irregular rudimentary teeth found in the young state, the entire dentition is reduced to a single pair, which lie horizontally in the upper jaw, and both of which in the female remain permanently concealed within the bone, so that this sex is practically toothless, while in the male the right tooth usually remains similarly concealed and abortive, and the left is immensely developed, attaining a length equal to more than half that of the entire animal, projecting horizontally from the head in the form of a cylindrical or slightly tapering pointed tusk, with the surface marked by spiral grooves or ridges.

The meaning and utility of some of these strange modifications it is impossible, in the imperfect state of our knowledge of the habits of the Cetacea, to explain, but the fact that in almost every case a more full number of rudimentary teeth is present in early stages of existence, which either disappear, or remain as concealed and functionless organs, points to the present condition in the aberrant and specialised forms as being one derived from the more generalised type, in which the teeth were numerous and equal.

The Mystacocetes, or Whalebone Whales, are distinguished by entire absence of teeth, at all events after birth. But it is a remarkable fact, first demonstrated by Geoffrey St. Hilaire, and since amply confirmed by Cuvier, Eschricht, Julin, and others, that in the fœtal state they have numerous minute calcified teeth lying in the dental groove of both upper and lower jaws. These attain their fullest development about the middle of fœtal life, after which period they are absorbed, no trace of them remaining at the time of birth. Their structure and mode of development has been shown to be exactly that characteristic of ordinary mammalian teeth, and it has also been observed that those at the posterior part of the series are larger, and have a bilobed form of crown, while those in front are simple and conical, a fact of considerable interest in connection with speculations as to the history of the group.

It is not until after the disappearance of these teeth that the baleen, or whalebone, makes its appearance. This remarkable structure, though, as will be presently shown, only a modification of a part existing in all mammals, is, in its specially developed condition as baleen, peculiar to one group of whales. It is therefore perfectly in accord with what might have been expected, that it is comparatively late in making its appearance. Characters that are common to a large number of species appear early, those that are special to a few, at a late period; alike both in the history of the race and of the individual.

Baleen consists of a series of flattened, horny plates, several hundred in number, on each side of the palate, separated by a bare interval along the middle line. They are placed transversely to the long axis of the palate, with very short spaces between them. Each plate or blade is somewhat triangular in form, with the base attached to the palate, and the apex hanging downwards. The outer edge of the blade is hard and smooth, but the inner edge and apex fray out into long, bristly fibres, so that the roof of the whale's mouth looks as if covered with hair, as described by Aristotle. The blades are longer near the middle of the series, and gradually diminish near the front and back of the mouth. The horny plates grow from a dense fibrous and highly vascular matrix, which covers the palatal surface of the maxillæ, and which sends out lamellar processes, one of which penetrates the base of each blade. Moreover, the free edge of these processes is covered with very long vascular thread-like papillæ, one of which forms the central axis of each of the hair-like epidermic fibres of which the blade is mainly composed. A transverse section of fresh whalebone shows that it is made up of numbers of these soft vascular papillæ, circular in outline, each surrounded by concentrically arranged epidermic cells, the whole bound together by other epidermic cells, which constitute the smooth cortical (so-called "enamel") surface of the blade, and which, disintegrating at the free edge, allows the individual fibres to become loose and to assume the hair-like appearance spoken of before These fibres differ from hairs in not being formed in depressed follicles in the enderon, but rather resemble those of which the horn of the rhinoceros is composed. The blades are supported and bound together for a certain

distance from their base, by a mass of less hardened epithelium, secreted by the surface of the palatal membrane or matrix of the whalebone in the intervals of the lamellar processes. This is the "intermediate substance" of Hunter, the "gum" of the whalers.

The function of the whalebone is to strain the water from the small marine mollusks, crustaceans, or fish upon which the whales subsist. In feeding they fill the immense mouth with water containing shoals of these small creatures, and then, on their closing the jaws and raising the tongue, so as to diminish the cavity of the mouth, the water streams out through the narrow intervals between the hairy fringe of the whalebone blades, and escapes through the lips, leaving the living prey to be swallowed. Almost all the other structures to which I am specially directing your attention, are, as I have mentioned, in a more or less rudimentary state in the Cetacea; the baleen, on the other hand, is an example of an exactly contrary condition, but an equally instructive one, as illustrating the mode in which nature works in producing the infinite variety we see in animal structures. Although appearing at first sight an entirely distinct and special formation, it evidently consists of nothing more than the highly modified papillæ of the lining membrane of the mouth, with an excessive and cornified epithelial development.

The bony palate of all mammals is covered with a closely-adhering layer of fibrovascular tissue, the surface of which is protected by a coating of non-vascular epithelium, the former exactly corresponding to the derm or true skin, and the latter to the epiderm of the external surface of the body. Sometimes this membrane is perfectly smooth, but it is more often raised into ridges, which run in a direction transverse to the axis of the head, and are curved with the concavity backwards; the ridges moreover do not extend across the middle line, being interrupted by a median depression or *raphé*. Indications of these ridges are clearly seen in the human palate, but they attain their greatest development in the Ungulata. In oxen, and especially in the giraffe, they form distinct laminæ, and their free edges develope a row of papillæ, giving them a pectinated appearance. Their epithelium is thick, hard, and white, though not horny. Although the interval between the structure of the ridges in the giraffe's palate and the most rudimentary form of baleen at present known is great, there is no difficulty in seeing that the latter is essentially a modification of the former, just as the hoof of the horse, with its basis of highly developed vascular laminæ and papillæ, and the resultant complex arrangement of the epidermic cells, is a modification of the simple nail or claw of other mammals, or as the horn of the rhinoceros is only a modification of the ordinary derm and epiderm covering the animal's body differentiated by a local exuberance of growth.

(*To be continued.*)

THE PERAK TIN-MINES[1]

THIS interesting memoir, which forms part of the *Archives des Missions scientifiques et littéraires*, série iii. vol. ix., gives the result of a seven months' exploration of the Malay State of Perak, made by the author, who was sent by the French Government upon a mission of scientific inquiry into the Malay Archipelago in 1881. Perak, although an insignificant unit among even the smallest States of the world, its extreme dimensions being only 95×50 miles, or an area of less than 5000 square miles, has long been known as a tin-producing country, being mentioned in the narratives of Tavernier, and the Dutch and Portuguese navigators of the seventeenth century; but it is only since the large influx of Chinese miners, consequent upon the suppression of the Taeping rebellion, that it has become of first-rate importance.

[1] "Les Mines d'Étain de Perak." Par J. Errington de la Croix. 8vo. Paris, 1882.)

The success attained by the first-comers led to a rapid increase of the Chinese population, who arrived in such numbers as to be soon beyond the control of the feeble Malay Government, and the mining being carried on without any regulations as to boundaries, the miners became divided into two parties, who made war upon each other with varying success, the Sultan looking on impartially during the contest, but siding with the winners. The defeated party in 1872 having taken to piracy at sea, was suppressed by English gunboats, and a resident was appointed for the purpose of keeping order; but the Malays having revolted in 1875, when the resident was murdered, the country has since been placed under a British protectorate, with a native rajah, under the title of Regent. This has been attended with the happiest results, the country having made great progress during the last six years, under the vigorous and enlightened management of the resident, Hugh Low, Esq., C.M.G., and now bids fair, according to the author, to become the most considerable producer of tin in the world.

The mines worked up to the present are entirely alluvial or stream works, the watercourses being filled with sand and gravel deposits to a depth of 20 or 30 feet, resting upon a floor of pure china clay, apparently derived from the decomposition of the granitic rocks forming the numerous parallel ridges which traverse the country from north to south. The geological description is necessarily imperfect owing to the dense tropical vegetation which covers the entire county; but the author has been able to establish the presence of numerous quartz veins traversing the granites which are coarsely porphyritic in the centre and largely charged with tourmaline at the edges of the masses, in fact reproducing the phenomena observed in the north-western tin districts of Cornwall. No mines have as yet been opened in any of these veins, but the author speaks of blocks of tin ore weighing more than 1 cwt. as having been found in the immediate vicinity of the hills, which are evidently not far removed from their original position. The bulk of the production is, however, derived from smaller rounded crystalline masses and grains contained in the lower part of the alluvial gravel, the workable thickness ranging from 7 to 10 feet, and the proportion of clean ore or "black tin" from about 1 to 4½ per cent. by weight. This is remarkable for its purity, being almost entirely free from wolfram, arsenic, and other foreign substances, which are so troublesome to the Cornish tin-miner. The methods of working, mechanical preparations, and smelting of the ore are of the simplest possible kind, the work, with the exception of a few centrifugal steam-pumps, and of Chinese chain-pumps driven by water-wheels, being entirely carried out by manual labour, with furnaces and other appliances of the most primitive types. This simplicity adds considerably to the interest of the author's detailed and carefully illustrated description, which enables the reader to realise in imagination the conditions prevailing in our western districts in the days when the Phœnicians traded with the Cornish miners for tin at St. Michael's Mount. Under the new British rule, the country has made rapid progress, the output of tin having risen from 2059 tons in 1876 to 5994 tons in 1881, the whole of which is exported through Penang. As at the latter date the cost of production, including revenue charges of about 17*l*., was estimated at about 61*l*. per ton, while the local selling price was 88*l*., showing a profit of 45 per cent., the popularity of the business is sufficiently explained. It is not probable, however, that such large profits will continue to be realised after the more productive deposits have been exhausted. It does not appear from the narrative that European labour of any kind is employed, the workpeople belonging to three races, namely, Malay aborigines, Klings or coolies from Madras and the Malabar coast, and Chinese, the latter supplying the whole of the miners, smelters

and other artisans directly employed in producing the metal. The author has a very high opinion of the Chinese miners, who are described as sober, regular in work, and accustomed to cooperative enterprises, against which, however, must be set the defects of being addicted to excess in opium and gambling, besides being very quarrelsome and exceedingly superstitious. The latter failing is, however, of interest as reproducing the old European legends of guardian genii of the mine, the "Kobads" of Germany and "Knockers" of Cornwall, who require to be propitiated by sacrifices and kept in good humour by orderly behaviour on the part of the miners. Infractions of the last rules are punished by the withdrawal of the guardian gnome, who takes all the unwrought ore in the mine away with him.

The execution of the work, both as regards illustration and typography, are exceedingly good, and reflect great credit upon the French National Printing Office.

H. B.

THE SIZE OF ATOMS[1]

FOUR lines of argument founded on observation have led to the conclusion that atoms or molecules are not inconceivably, not immeasurably small. I use the words "inconceivably" and "immeasurably" advisedly. That which is measurable is not inconceivable, and therefore the two words put together constitute a tautology. We leave inconceivableness in fact to metaphysicians. Nothing that we can measure is inconceivably large or inconceivably small in physical science. It may be difficult to understand the numbers expressing the magnitude, but whether it be very large or very small there is nothing inconceivable in the nature of the thing because of its greatness or smallness, or in our views and appreciation and numerical expression of the magnitude. The general result of the four lines of reasoning to which I have referred, founded respectively on the undulatory theory of light, on the phenomena of contact electricity, on capillary attraction, and on the kinetic theory of gases, agrees in showing that the atoms or molecules of ordinary matter must be something like the 1/10,000,000, or from the 1/10,000,000 to the 1/100,000,000 of a centimetre in diameter. I speak somewhat vaguely, and I do so, not inadvertently, when I speak of atoms and molecules. I must ask the chemists to forgive me if I even abuse the words and apply a misnomer occasionally. The chemists do not know what is to be the atom; for instance, whether hydrogen gas is to consist of two pieces of matter in union constituting one molecule, and these molecules flying about; or whether single molecules each indivisible, or at all events undivided in chemical action, constitute the structure. I shall not go into any such questions at all, but merely take the broad view that matter, although we may conceive it to be infinitely divisible, is not infinitely divisible without decomposition. Just as a building of brick may be divided into parts, into a part containing 1000 bricks, and another part containing 2500 bricks, and those parts viewed largely may be said to be similar or homogeneous; but if you divide the matter of a brick building into spaces of nine inches thick, and then think of subdividing it farther, you find you have come to something which is atomic, that is, indivisible without destroying the elements of the structure. The question of the molecular structure of a building does not necessarily involve the question, Can a brick be divided into parts, and can those parts be divided into much smaller parts? and so on. It used to be a favourite subject for metaphysical argument amongst the schoolmen whether matter is infinitely divisible, or whether *space* is infinitely divisible, which some maintained, whilst others maintained only that *matter* is not infinitely divisible, and demonstrated that there is nothing inconceivable in the infinite subdivision of space. Why, even time was divided into moments (time-atoms!), and the idea of continuity of time was involved in a halo of argument, and metaphysical—I will not say absurdity—but metaphysical word-fencing, which was no doubt very amusing for want of a more instructive subject of study. There is in sober earnest this very important thing to be attended to, however, that in chronometry as in geometry, we have absolute continuity, and it is simply an inconceivable absurdity to suppose a limit to smallness whether of time or of space. But on the other hand, whether we can divide a piece of glass into pieces smaller than the 1/100,000 of a centimetre in diameter, and so on without breaking it up, and making it cease to have the properties of glass, just as a brick has not the property of a brick wall, is a very practical question, and a question which we are quite disposed to enter upon.

I wish in the beginning to beg you not to run away from the subject by thinking of the exceeding smallness of atoms. Atoms are not so exceedingly small after all. The four lines of argument I have referred to make it perfectly certain that the molecules which constitute the air we breathe are not very much smaller, if smaller at all, than 1/10,000,000 of a centimetre in diameter. I was told by a friend just five minutes ago that if I give you results in centimetres you will not understand me. I do not admit this calumny on the Royal Institution of Great Britain; no doubt many of you as Englishmen are more familiar with the unhappy British inch; but you all surely understand the centimetre, at all events it was taught till a few years ago in the primary national schools. Look at that diagram (Fig. 1), as I want you all to understand an

One centimetre. One millimetre.

Fig. 1.

inch, a centimetre, a millimetre, the 1/10 of a millimetre, and the 1/100 of a millimetre, the 1/1,000 of a millimetre, and the 1/1,000,000 of a millimetre. The diagram on the wall represents the metre; below that the yard; next the decimetre, and a circle of a decimetre diameter, the centimetre and a circle of a centimetre, and the millimetre, which is 1/10 of a centimetre, or in round numbers 1/40 of an inch. We will adhere however to one simple system, for it is only because we are in England that the yard and inch are put before you at all, among the metres and centimetres. You see on the diagram then the metre, the centimetre, the millimetre, with circles of the same diameter. Somebody tells me the millimetre is not there; I cannot see it, but it certainly is there, and a circle whose diameter is a millimetre, both accurately painted in black. I say there is a millimetre and you cannot see it. And now imagine *there* is 1/10 of a millimetre, and *there* 1/100 of a millimetre and 1/1000 of a millimetre, and *there* is a round atom of oxygen 1/1,000,000 of a millimetre in diameter. You see them all.

Now we must have a practical means of measuring, and optics supply us with it for thousandths of a millimetre. One of our temporary standards of measurement shall be the wave-length of light; but the wave-length is a very indefinite measurement, because there are wave-lengths for different colours of light, visible and invisible, in the ratio of 1 to 16. We have, as it were—borrowing an analogy from sound—four octaves of light that we know of. How far the range in reality extends above and below the range hitherto measured, we cannot even guess in the present state of science. The table before you (Table I.) gives you an idea of magnitudes of length,

[1] A lecture delivered by Sir William Thomson at the Royal Institution, on Friday, February 2. Revised by the Author.

TABLE I.—*Data for Visible Light.*

Line of Spectrum.		Wave-length in Centimetres.		Wave Frequency, or number of periods per second.
A	...	$7 \cdot 604 \times 10^{-5}$	...	$395 \cdot 0 \times 10^{12}$
B	...	6·867 ,,	...	437·3 ,,
C	...	6·562 ,,	...	457·7 ,,
D_1	...	5·895 ,,	...	509·7 ,,
D_2	...	5·889 ,,		
E	...	5·269 ,,	...	570·0 ,,
b	...	5·183 ,,	...	
F	...	4·861 ,,	...	617·9 ,,
G	...	4·307 ,,	...	697·3 ,,
H_1	...	3·968 ,,	...	756·9 ,,
H_2	...	3·933 ,,	...	763·6 ,,

and again of small intervals of time. In the column on the left you have the wave-length of light in fractions of a centimetre; the unit in which these numbers to the left is measured is the 1/100,000 (or 10^{-5}) of a centimetre. We have then, of visible light, wave-lengths from $7\frac{1}{2}$ to 4 nearly, or 3·9. You may say then roundly, that for the wave-lengths of visible light, which alone is what is represented on that table, we have wave-lengths of from 4 to 8 on our scale of 1/100,000 of a centimetre. The 8 is invisible radiation a little below the red end of the spectrum. The lowest, marked by Fraunhofer with the letter *A*, has for wave-length $7\frac{1}{2}$/100,000 of a centimetre. On the model before you I will now show you what is meant by a "wave-length;" it is not length along the crest, such as we sometimes see well marked in a breaking wave of the sea, on a long straight beach; it is distance from crest to crest of the waves. [This was illustrated by a large number of horizontal rods of wood connected together and suspended bifilarly by two threads in the centre hanging from the ceiling;[1] on moving the lowermost rod, a wave was propagated up the series.] Imagine the ends of those rods to represent particles. The rods themselves let us suppose to be invisible, and merely their ends visible, to represent the particles acting upon one another mutually with elastic force, as if of india-rubber bands, or steel spiral springs, or jelly, or elastic material of some kind. They do act on one another in this model through the central mounting. Here again is another model illustrating waves (Fig. 2).[2] The white circles on the wooden rods represent pieces of matter—I will not say molecules at present, though we shall deal with them as molecules afterwards. Light consists of vibrations transverse to the line of propagation, just as in the models before you.

[1] The details of this bifilar suspension need not be minutely described, as the new form, with a single steel pianoforte wire to give the required mutual forces, described below and represented in Fig. 2, is better and more easily made.

[2] This apparatus, which is represented in the woodcut, Fig. 2, is of the following dimensions and description. The series of equal and similar bars (B) of which the ends represent molecules of the medium, and the pendulum bar (P), which performs the part of exciter of vibrations, or of kinetic store of vibrational energy, are pieces of wood each 50 centimetres long, 3 centimetres broad, and 1·5 centimetres thick. The suspending wire is steel pianoforte wire No. 22 B W.G. (·07 of a cm. diameter), and the bars are secured to it in the following manner. Three brass pins of about ·4 of a centimetre diameter are fitted loosely in each bar in the position as indicated; *i.e.* forming the corners of an isosceles triangular figure, with its base parallel to the line of the suspending wire, and about 1 mm. to one side of it. The suspending wire, which is laid in grooves cut in the pins, is passed under the upper pin, outside the pin at the apex of the triangle, over the upper side of the lower pin, and thence down to the next bar. The upper end of this wire is secured by being taken through a hole in the supporting beam and several turns of it put round a pin placed on one side of the hole, as indicated in the diagram. To each end of the pendulum bar is made fast a steel spiral spring as shown; the upper ends of these springs being secured to short cords which pass up through holes in the supporting beam, and are fastened by two or three turns taken round the pins. These steel springs serve as potential stores of vibrational energy alternating in each vibration with the kinetic store constituted by the pendulum bar. The ends of the vibrating bars (B) are loaded with masses of lead attached to them. The much larger masses of lead seen on the pendulum bar, which are adjustable to different positions on the bar, are, in the diagram, shown at the smallest distance apart. The lowermost bar carries two vanes of tin projecting downwards, which dip into viscous liquid (treacle diluted with water) contained in the vessel (*c*). A heavy weight resting on the bottom of this vessel, and connected to the lower end of the suspending wire by a stretched indiarubber band, serves to keep the lower end of the apparatus in position. The period of vibration of the pendulum bar is adjustable to any desired magnitude by shifting in or out the attached weights, or by tightening or relaxing the cords which pull the upper ends of the spiral springs.

Now in that beautiful experiment well known as Newton's rings we have at once a measure of length in

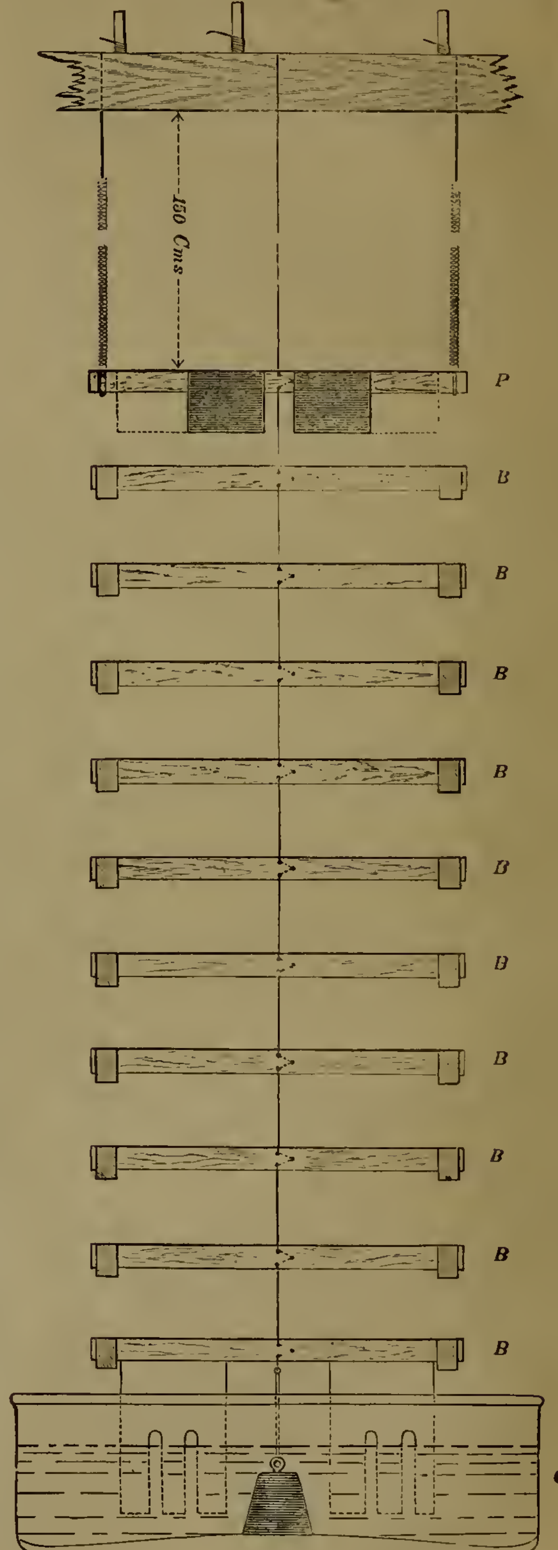

FIG. 2.

the distance between two pieces of glass to give any par-

ticular tint of colour. The wave-length you see, in the distance from crest to crest of the waves travelling up the long model when I commence giving a simple harmonic oscillation to the lowest bar. I have here a convex lens of very long focus, and a piece of plate glass with its back blackened. When I press the piece of glass against the glass blackened behind, I see coloured rings; the phenomenon will be shown to you on the screen by means of the electric light reflected from the space of air between the two pieces of glass. This phenomenon was first observed by Sir Isaac Newton, and was first explained by the undulatory theory of light. [Newton's rings are now shown on the screen before you by reflected electric light.] If I press the glasses together, you see a dark spot in the centre; the rings appear round it, and there is a dark centre with irregularities. Pressure is required to produce that spot. Why? The answer generally given is, because glass repels glass at a distance of two or three wave-lengths of light; say at a distance of 1/5,000 of a centimetre. I do not believe that for a moment. The seeming repulsion comes from shreds or particles of dust between them. The black spot in the centre is a place where the distance between them is less than a quarter of a wave-length. Now the wave-length for yellow light is about 1/17,000 of a centimetre. The quarter of 1/17,000 is about 1/70,000. The place where you see the middle of that black circle corresponds to air at a distance of less than 1/70,000 of a centimetre. Passing from this black spot to the first ring of maximum light, add half a wave-length to the distance, and we can tell what the distance between the two pieces of glass is at this place; add another half wave-length, and we come to the next maximum of light again; but the colour prevents us speaking very definitely because we have a number of different wave-lengths concerned. I will simplify that by reducing it all to one colour, red, by interposing a red glass. You have now one colour, but much less light altogether, because this glass only lets through homogeneous red light, or not much besides. Now look at what you see on the screen, and you have unmistakable evidence of fulcrums of dust between the glass surfaces. When I put on the screw, I whiten the central black spot by causing the elastic glass to pivot, as it were, round the innumerable little fulcrums constituted by the molecules of dust; and the pieces of glass are pressed not against one another, but against these fulcrums. There are innumerable—say thousands—of little particles of dust jammed between the glass, some of them of perhaps 1/3,000 of a centimetre in diameter, say 5 or 6 wave-lengths. If you lay one piece of glass on another, you think you are pressing glass on glass, but it is nothing of the kind; it is glass on dust. This is a very beautiful phenomenon, and my first object in showing this experiment was simply because it gives us a linear measure bringing us down at once to 1/100,000 of a centimetre.

Now I am just going to enter a very little into detail regarding the reasons that those four lines of argument give us for assigning a limit to the smallness of the molecules of matter. I shall take contact electricity first, and very briefly. If I take these two pieces of zinc and copper and touch them together at the two corners, they become electrified, and attract one another with a perfectly definite force, of which the magnitude is ascertained from absolute measurements in connection with the well-established doctrine of contact electricity. I do not feel it, because the force is very small. You may do the thing in a measured way; you may place a little metallic knob or projection on one of them of 1/100,000 of a centimetre, and lean the other against it. Let there be three such little metal feet put on the copper; let me touch the zinc plate with one of them, and turn it gradually down till it comes to touch the other two. In this position, with an air-space of 1/100,000 of a centimetre between them, there will be positive and negative electricity on the zinc and copper surfaces respectively, of such quantities as to cause a mutual attraction amounting to 2 grammes weight per square centimetre. The amount of work done by the electric attraction upon the plates while they are being allowed to approach one another with metallic connection between them at the corner first touched, till they come to the distance of 1/100,000 of a centimetre, is 2/100,000 of a centimetre-gramme, supposing the area of each plate to be one square centimetre.

(*To be continued.*)

DEATH OF THE PRESIDENT OF THE ROYAL SOCIETY

It is with the profoundest regret that we announce the death of Mr. Spottiswoode, the President of the Royal Society, at 11.15 yesterday morning. The bulletin issued on Tuesday to the effect that although there was no hemorrhage, still that there was no improvement in Mr. Spottiswoode's condition, boded ill because those who knew him best feared that a reserve of strength, which might perhaps have made way against the further progress of the fever through its later stages, was wanting.

As the sad news reaches us just as we are going to press, and as indeed we so recently entered at some considerable length into the lifework of him who is now no more, there is no necessity for us on the present occasion to do more than make the above announcement. This, however, must be said: that there is hardly a man of science in this country, and there are very many in other countries, who will not feel that they have lost a true friend, and one of whose friendship any man might have been proud. There is little doubt too that if he had been more sparing of himself in the various duties which were incumbent upon him as President of the Royal Society, if he had not so freely given all his thoughts and all his exertions to any scientific question which was going on, there might have been more time for relaxation, and there might have been strength to have tided over the illness which has now laid him low.

NOTES

We regret to have to announce the death of General Sir Edward Sabine, K.C.B., which occurred on the 26th inst. at Richmond, where he had been residing for the last twelve months. He was in his ninety-fifth year, having been born October 14, 1788.

At the meeting of the Paris Academy of Sciences on Monday last week the following message concerning the eclipse observations from M. Janssen, dated San Francisco, was read:—"*Janssen:* discovery of the Fraunhofer spectrum and the dark lines of the solar spectrum in the corona, showing cosmical matter around the sun. Large photographs of the corona and the circumsolar regions to a distance of 15°, in search for intra-Mercurial planets. *Palisa* and *Trouvelot:* Exploration of the circumsolar regions; no intra-Mercurial planets found. *Trouvelot:* Sketch of the corona. *Tacchini:* Polarisation of the corona and streamers; spectrum of the streamers, showing analogy

with the spectrum of comets; continuous spectrum corona; spectrum of protuberances; plates and drawings of protuberances."

THE American Association for the Advancement of Science will hold its thirty-second annual meeting at Minneapolis, Minn., August 15 and following days. The president-elect is Prof. C. A. Young of Princeton, and the following is the list of the sectional vice-presidents of the meeting:—Section A (Mathematics and Astronomy), W. A. Rogers of Cambridge; B (Physics), H. A. Rowland of Baltimore; C (Chemistry), E. W. Morley of Cleveland; D (Mechanical Science), De Volsen Wood of Hoboken; E (Geology and Geography), C. H. Hitchcock of Hanover; F (Biology), W. J. Beal of Lansing; G (Histology and Microscopy), J. D. Cox of Cincinnati; H (Anthropology), O. T. Mason of Washington; I (Economic Science and Statistics), F. B. Hough of Lowville. The permanent secretary is F. W. Putnam of Cambridge; the general secretary (of the meeting), J. R. Eastman of Washington.

THE annual meeting of the American Academy of Arts and Sciences was held in Boston, Tuesday, May 29. The following officers, we learn from *Science*, were elected for the ensuing year:—President, Prof. Joseph Lovering; vice-president, Dr. Oliver Wendell Holmes; corresponding secretary, Prof. Josiah P. Cooke; recording secretary, Prof. John Trowbridge; treasurer, H. P. Kidder; librarian, S. H. Scudder. M. Adolph Wurtz of Paris was elected a foreign honorary member. The list of members of the Academy now includes 192 resident Fellows, 92 associate Fellows, and 72 foreign honorary members. The Academy voted unanimously to confer the Rumford gold medal upon Prof. Henry A. Rowland of Baltimore for his researches in light and heat.

A NEW mode of measuring light was proposed at the last meeting of the Royal Society by Mr. Preece, F.R.S. The standard of reference is a small surface illuminated to a given intensity, and the mode of comparison is the light given by a small glow lamp whose state of incandescence is raised or lowered by increasing or diminishing an electric current. The amount of illumination is measured by the amount of current flowing, so that the number of amperes gives the degree of illumination. The standard surface is that illuminated by a British "candle" at 12·7 inches, and this is the same as that produced by the French "bec" at 1 metre distance. In this way sunlight, moonlight, twilight, fog, and the amount of illumination in any part of a room or building, or that distributed over a street or area at any time of day or night can be measured without any reference to the source of light or its distance from the point lighted. We have in fact a standard of illumination very easily and simply measured.

PROF. BUREAU has been appointed Director of the Jardin des Plantes in place of the late M. Decaisne.

ON Saturday, June 16, a joint meeting of the Essex Field Club and the Geologists' Association was held at Grays for the purpose of visiting the "Deneholes" in Hangman's Wood. From fifty to sixty members and visitors, including many members of the Anthropological Institute, were present, and nearly all had an opportunity of descending one or both of the two holes which were exhibited for the occasion. The meeting was under the conductorship of Mr. T. V. Holmes, F.G.S., who has written a paper giving an account of last year's preliminary exploration, which will shortly appear in the *Transactions of the Essex Field Club*. Photographs of the interior of one of the holes were successfully taken by Mr. A. J. Spiller by means of magnesium burning in oxygen. The party assembled for tea at the "King's Arms" Hotel, when the president of the Club, Prof. G. S. Boulger, and Mr. Holmes announced that it was the intention of the Club to undertake the systematic investigation of these interesting prehistoric remains, both at Grays and elsewhere along the Essex shore of the Thames. A large fund will be required for this work, and a committee has been formed for the purpose of organising the explorations, which will be carried on under the personal superintendence of Mr. T. V. Holmes and Mr. F. C. J. Spurrell. After some remarks by Dr. Hicks, the president of the Geologists' Association, the meeting broke up. A public appeal for assistance will shortly be made, and in the meantime subscriptions will be gladly received by the treasurer of the Essex Field Club, Mr. Andrew Johnston, J.P., The Firs, Woodford, or by the Hon. Secretary, Mr. William Cole, Laurel Cottage, Buckhurst Hill, to be paid to the account of the "Denehole Exploration Fund."

IT will be seen from our Correspondence Columns that an earthquake was felt in the south-west of England on Monday. The shock seems to have spread very widely over Devonshire and East Cornwall. At Holsworthy, Devonshire, a very perceptible shock was felt at seventeen minutes to two o'clock that afternoon. Floors shook, and doors and windows rattled as from a passing train. No damage is reported. A severe shock was felt at Hartland and Clovelly at 1.30 p.m., and a second shock at Clovelly at 1.40. Houses shook considerably, and the bottles on counters in shops were knocked against each other. A similar statement is sent from Bude. The inhabitants of Princetown and the vicinity of Dartmoor, about two o'clock were startled by two smart shocks, followed by a subterranean rumbling like the passing of a very heavy waggon, or the echo of distant thunder. The first trembling was of sufficient intensity to be perceptibly felt by those who happened to be occupying a chair, and the like effect was produced on small movable objects, but it resulted in no mischief. The disturbances apparently travelled from north east to west. At Launceston at twenty minutes to two a shock was felt, accompanied by a rumbling noise, which lasted at intervals during about thirty minutes. The houses shook, and china and earthenware rattled on the shelves. About an hour afterwards another shock was felt, but not so severe. Similar information comes from Lostwithiel, Liskeard, Lydford, Tavistock, Okehampton, and Bideford.

THE Fine Art Society (148, New Bond Street) have sent us an artist's proof of M. Leopold Flameng's very fine etching after Mr. John Collier's picture of the late Mr. Darwin. The original is admittedly faithful and characteristic, and of high rank as a work of art, and M. Flameng has been perfectly successful in reproducing the artist's intention. The result of both these labours is a portrait of the greatest man of science of this century, which all other men of science should be glad to possess. We believe the number printed is limited. M. Flameng will also undertake a similar etching of Mr. Collier's picture of Prof. Huxley in this year's Exhibition.

WE have received the Report of the Royal Victoria Coffee Hall, where, as may be known to many of our readers, much good work is being done at the present time in the way of providing cheap amusement every night, free from the temptation to drink and other evils common to ordinary music halls. Among other experiments being tried are short lectures of the simplest and most popular kind, generally on some scientific subject illustrated by the oxyhydrogen lantern. We are told that a really good lecturer who understands his audience as well as his subject meets with a most encouraging reception, but that very few men of science give their assistance in this good work. We regret this; but we believe it is largely due to the fact that very little is known of the work in question, and that if a general appeal were made to those men of science who occasionally give an account either of their own work or the work of others, many would be found willing to join in the

effort which is now being made to interest the working classes in science in what was formerly the Royal Victoria Theatre.

OUR Paris Correspondent writes:—An interesting experiment took place on June 24, at the early hour of 3.45 in Paris, for the purpose of testing the capacity of accumulators of the French Storage Company to move tramcars. We travelled up to La Muette and back, a distance of 30 kilometres, in about three hours and twenty minutes, including stoppages and loss of time incurred by several incidents. The road has many steep inclines, which were ascended without difficulty. The mean velocity exceeded 10 kilometres per hour. The electricity was supplied by seventy accumulators, weighing 30 kilograms each, which were placed under the seats. At starting the potential was 140 volts, and having completed its task the current was as high as 126, so that at least 10 kilometres more could have been run if deemed necessary. This run is the longest on record made by electricity. M. Philippart was directing the operations.

THE Balloon Exhibition was closed at the Trocadéro on the 24th inst. It was visited by two officers of the British army, sent by the Government to report. Among the notable objects we may mention the original valve used by Gay-Lussac in his ascent, a new valve used by French aëronauts, the car and net of Lhoste as rescued from the North Sea, a panoramic apparatus for photographing a bird's-eye view of scenery as seen from a balloon at an altitude of 200 metres, several photographs taken from the cars of captive or free balloons in Paris, Boston, and Rouen, a refrigerator by Mignon and Bouard for instantly condensing vapour from clouds, bichromate elements constructed by Trouvé for Tissandier's intended aërial experiments.

THE following are the details of the method by which the fairy-like illuminations at Moscow at the coronation were produced:—The Tower of Ivan the Great and its side galleries were lit up by 3,500 small Edison lamps, fed by eighteen portable engines, which moved a number of dynamo-electric machines of every existing system. The portable engines and machines were kept at the other bank of the Moskwa. The sheds communicated with the tower by seventy aërial electric wires. On the ramparts of the Kremlin towards the river eight large and ten smaller electric suns threw their light over the river. The rest of the illuminations consisted of 200,000 lamps and 30,000 coloured glass globes, 50,000 lanterns of Venetian glass, 600,000 tapers, and 10,800 lb. of fireworks.

THE National Museum at Washington is one of the best examples in the United States of the practical application of electricity. In so large a building it was found advisable to take advantage of the best means of communication, first being its system of telephones and call-bells, by which those in any room can communicate with every room in the building. Twenty-six telephones are connected by a local telephone exchange, which in turn is connected with the main telephone office of the city. The result is that but three messengers are needed in this vast establishment. The photographic laboratory is independent of the sun, owing to the electric light there used. If one of the 850 windows or 230 doors is opened, a bell rings, and an electric annunciator shows to an attendant at the main office which window or door it is. This system is soon to be applied to every case of specimens. The watchmen at night, also, are kept to their posts by hourly releasing an electric current at certain stations, which pierces a dial and records their visit. The sixteen clock dials are likewise run by electric currents.

A MONUMENT to the memory of the celebrated naturalist, Lorenz Oken, will be unveiled at Offenburg on August 1 next. It will be in the shape of a fountain crowned with a marble bust of Oken.

MESSRS. GRIFFITH AND FARRAN have issued a new and cheaper edition of Mrs. Lankester's "Talks about Plants; or Early Lessons in Botany," first published in 1878.

PRINCE LUDWIG FERDINAND of Bavaria, an indefatigable worker in the domain of comparative anatomy, is about to publish a monograph on the tongue. Riedel (Munich) will be the publisher.

A MAGNIFICENT meteor was observed at Giesshübl, near Mödling (Vienna), on June 3, at 9.44 p.m. It seemed to consist of two fireballs, an emerald green one followed by a red one. They both moved apparently at a not very great altitude in the direction south-east to north west. The phenomenon lasted for three seconds. It is remarkable that the meteor seen at the same place on the evening of March 13, moved in almost exactly the same direction. Also at Gau-Algesheim (near Mainz) a fine meteor was seen in the northern sky on the evening of June 3; it left a most vivid trail behind, which shone for some time along the whole extent of its path.

A WRITER in the *North China Herald* gives some curious information respecting the foot-measure in China. At present it varies largely in different parts of the country and according to different trades; thus the foot of the carpenter's rule at Ningpo is less than ten, while that of the junk-builders at Shanghai is nearly sixteen, inches. But a medium value of twelve inches is not uncommon. The standard foot of the Imperial Board of Works at Peking is twelve and a half inches. A copper foot-measure, dated A.D. 81, is still preserved, and is nine and a half inches in length. The width is one inch. The small copper coins, commonly called *cash*, were made of such a size, sometimes, as just to cover an inch on the foot-rule. In the course of two centuries it was found that the foot had increased half an inch, and a difference in the dimensions of musical instruments resulted. Want of harmony was the consequence, and accordingly in A.D. 274 a new measure, exactly nine inches in length, was made the standard. Among the means employed for comparing the old and new foot are mentioned the gnomon of official sundials, and the length of certain jade tubes used according to old regulations as standards. One of these latter was so adjusted that an inch in breadth was equal to the breadth of ten millet seeds. A hundred millet seeds, or ten inches, was the foot. The Chinese foot is really based on the human hand, as is the European foot upon the foot. It strikes the Chinese as very incongruous when they hear that we measure cloth, woodwork, masonry, &c., which they regard as especially matters for the hand, by the foot. Of the jade tubes above mentioned there were twelve, and these formed the basis for the measurement of liquids and solids four thousand years ago. They are mentioned in the oldest Chinese documents with the astrolabe, the cycle of sixty years, and several of the oldest constellations. It is likely that they will be found to be an importation from Babylon, and in that case the Chinese foot is based on a Babylonian measure of a span, and should be nine inches in length.

MR. CHAS. G. LELAND, the writer of No. 4 (1882) of the "Circulars of Information" of the United States Bureau of Education, on the subject of Industrial Art in Schools, after premising that ornamental art is innate in man, and indeed is developed in a race before it attains proficiency in the useful, and remarking that the brains of the Parisians of the thirteenth century, when Gothic art adorned every object, were much smaller than they are now, draws the conclusion that children are more open to art education than to technical training. He finds the sexes equal in ability; urges outline drawing and monochrome as the foundation of further work; recommends the use of various mechanical helps, as of compasses and stencilling as actual incentives to freehand drawing; urges the practice of freehand

from the shoulder, even in the variety of drawing called writing; and gives a wonderful list of artistic effects which pupils who have had only short instruction in these arts are competent to produce. Education of this sort is valuable as simply affording healthy occupation of body and mind to some classes; it opens the eyes of the mind, which will tend to make work popular instead of idleness. He teaches that nothing made by machinery can be artistic; physical comforts may be supplied by it, but works of taste and refinement must be hand-made, and among the poorer classes should be the produce of home art, like the carved oak of Ann Hathaway's cottage. Mr. Leland was one of the first to point out that the decay of the apprentice system must soon necessitate industrial education, and he has prepared a series of cheap art-work manuals on decorative design, ceramic or porcelain painting, tapestry or dye-painting, outline and filled-in embroidery, decorative oil-painting, wood-carving, *repoussé* or sheet-brass work, leather work, papier mâché, modelling in clay, with underglaze faïence decoration, and stencilling.—No. 5 of the "Circulars" is on the subject of Maternal Schools in France, which answer to our Infant Schools. The value of them as laying the foundations of education is urged by the Commissioners. Excellent suggestions for object lessons, whose subjects are supplied by the season of the year, and also for the arrangement of school buildings are given. The result of such schools should be a slight training of the senses by object-lessons; the beginnings of habits and dispositions favourable to future education; a taste for gymnastics, for singing, and for drawing; an eagerness to listen, observe, question, and answer; the power of attention; a generally quickened intelligence, and a mind open to receive good moral influences. In other words, education is a "bringing forth" of the powers of the mind, and not a making it a live cyclopædia. No. 6 is a full copy, with a few useful notes for comparison, of the English Report of the Royal Commission on Technical Education in France, presented by Mr. Samuelson and his coadjutors in February, 1882.

WITH the May number the *Journal of Forestry* changed both its title and the colour and design of its cover, and it now appears under the simple name of *Forestry*. It is an acknowledged fact that changes of this character are generally inadvisable in a journal of long-established reputation, but under the editorship of Mr. Francis George Heath we have no doubt that *Forestry* will at least maintain the reputation and circulation it had attained under its old management, if it does not increase them, which indeed it is most likely to do. The May number opens with an editorial note entitled "A May Note," in which the glories of spring and summer in woodland glades and forest are set forth. Then Mr. R. D. Blackmore gives us "A Cuckoo Song." Amongst other readable articles may be mentioned "Lord Somerville; a forgotten President of Agriculture," by Mr. R. A. Kinglake; Mr. Boulger's "Beauties of British Trees," and Mr. Guillemard's "Forest Ramble in New South Wales." In the June number the same amount of interest and variety is maintained. Mr. Guillemard gives "A Forest Ramble in Norway." The article on "Epping Forest and its Future Management" will however, we have no doubt, be read by most readers, as any one having the slightest inclination towards any branch of natural history cannot fail to be interested in maintaining the Forest in all its native beauty, and if *Forestry* is able by its advocacy, backed up by the opinions of those who are now taking a lead in the matter, to stem the tide of improvements so-called in Epping Forest, it will have fulfilled a work for which thousands will be thankful.

THE additions to the Zoological Society's Gardens during the past week include a Crab-eating Raccoon (*Procyon cancrivorus* ♂) from Brazil, presented by Mr. Theo. Walsh; a Ring-tailed Coati (*Nasua rufa* ♂) from Brazil, presented by Mr. R. G. Hamilton; two Common Hedgehogs (*Erinaceus europæus*), British, presented by Mr. S. Mummery; four Restless Cavies (*Cavia caprera*) from Brazil, presented by Mr. E. H. Draper; a Ring-necked Parrakeet (*Palæornis torquatus*) from India, presented by Mr. W. Quail; two Common Kingfishers (*Alcedo ispida*), British, presented by Mr. T. E. Gunn; three Common Vipers (*Vipera berus*), British, presented by Mr. C. Taylor; two Common Snakes (*Tropidonotus natrix*), European, presented by Lord Arthur Russell, F.Z.S.; a Puma (*Felis concolor* ♀) from South America, a Goffin's Cockatoo (*Cacatua goffini*) from Queensland, deposited; two West African Love Birds (*Agapornis pullaria*) from West Africa, an Indian Python (*Python molurus*) from India, purchased; two Vulpine Phalangers (*Phalangista vulpina*), eight Gold Pheasants (*Thaumalea picta*), six Prairie Grouse (*Tetrao cupido*), a Herring Gull (*Larus argentatus*), bred in the Gardens.

OUR ASTRONOMICAL COLUMN

THE NEXT TOTAL SOLAR ECLIPSE.—In NATURE, vol. xiv. p. 450, we gave some results of an approximate calculation of the total eclipse of the sun on September 8–9, 1885, wherein the central line traverses New Zealand, but does not encounter land in any other part of its course. The correction required to the moon's place there employed is sufficiently important to render a new calculation of interest, and we shall accordingly present here some of the circumstances of the eclipse, resulting from the substitution of the lunar places in the *Nautical Almanac*, which are founded upon Hansen's Tables, with Prof. Newcomb's corrections. The elements of the eclipse as given in the ephemeris are employed, excepting that in place of Hansen's semidiameter of the moon, we infer the semidiameter from the ratio, 0.2725 of the horizontal parallax.

At a point in longitude 11h. 40m. 0s. E. of Greenwich, with 40° 49'·4 south latitude (nearly on the central line) the total eclipse begins, September 9, at 7h. 44m. 9s. local mean time, and continues 1m. 51s., and this will be about the longest duration of totality available for observation upon land in this eclipse. For any place near the above point, the Greenwich mean times of beginning and ending of totality may be obtained from the following formulæ:—

$$\text{Cos. } w = -116{\cdot}3108 - [2{\cdot}10869] \sin. l + [1{\cdot}64777] \cos. l \cos. (L - 161°\ 16'{\cdot}5)$$
$$t = 8\text{h. } 58\text{m. } 21{\cdot}1\text{s} \mp [1{\cdot}74578] \sin. w - [3{\cdot}37987] \sin. l$$
$$- [3{\cdot}85619] \cos. l \cos. (L - 145°\ 49'{\cdot}6).$$

Here L is the longitude from Greenwich, reckoned *positive*, and *l* the geocentric latitude, which may be deduced from Mr. Stone's valuable table in the *Monthly Notices of the Royal Astronomical Society* for January last, a table it might have been worth while to publish separately. The quantities in square brackets are logarithms.

As one result of the introduction of the more accurate place of the moon, it is found that the central line approaches much nearer to Wellington; a direct calculation for that place shows that the total eclipse begins there at 7h. 44m. 23s. a.m., and ends at 7h. 45m. 46s. local mean time, thus continuing 1m. 23s., and the same figures are given by the above equations. At Nelson totality commences at 7h. 37m. 16s. a.m. local mean time, and continues 1m. 3s.

It may be noted that during the totality of this eclipse the planet Jupiter will be situated only 45' from the sun's limb, on an angle of about 26° with the circle of declination at his centre.

THE ANNULAR SOLAR ECLIPSE OF OCTOBER 31, 1883.—In May last we had a case where the track of a total eclipse of the sun was almost wholly an ocean-track, and where it was consequently necessary to send expeditions to the Mid-Pacific, to obtain observations. The annular eclipse in October next is similarly circumstanced; excepting possibly one or two mere rocks in the Pacific, it will not be observable on land, elsewhere than on the island of Niphon, Japan. If we calculate from the *Nautical Almanac* elements for longitude 9h. 20m. 48s. E. and latitude 38° 11' N., we find the annular phase commences at 7h. 28m. 2s. a.m., and ends at 7h. 35m. 23s., a duration of 7m. 21s., and the sun will be at an altitude of about 12°. At the capital, Tokio, the eclipse will not be annular; the greatest phase is at 7h. 28m. a.m., magnitude 0·88 (the sun's diameter being taken as unity).

THE GREAT COMET OF 1882.—In No. 2521 of the *Astronomische Nachrichten* is an elliptical orbit of this comet by Mr. John Tatlock, jun., of Williamstown, Mass., with a period of 1376 years, which, as Prof. Krueger remarks in a note, differs materially from the results of Kreutz, Frisby, and Fabritius. It may be added that the new calculation can have little weight, being founded upon normals for October 8, November 24, and January 29, so that at the date of the first normal the comet was already far past the perihelion, and in fact during the whole interval only described a heliocentric arc of about 5° 10'. Dr. Kreutz has shown the possibility of closely representing by the same orbit the anteperihelion observations and those made subsequently to perihelion passage, though there may be need of much more minute discussion before it can be safely assumed that there was absolutely no appreciable effect from the comet's passage through the solar coronal region.

GEOGRAPHICAL NOTES

Science announces that Lieut. Schwatka, accompanied by Assistant-Surgeon Wilson, C. A. Homan, U.S. Engineer Corps, and three private soldiers, left for Chilkat, Alaska, May 22, from Portland, Or., on the steamer *Victoria*. They are provisioned for a six months' cruise, will employ Indians for packers, &c., and intend to ascend the Chilkat River to its head, make the passage to the head waters of the Lewis River, and descend the same to its junction with the Yukon, and descend the Yukon River to its mouth. It is said to be their intention to survey the course of these rivers; and there is no doubt that a properly qualified and equipped party would find abundance of useful work ready to their hands. The whole route has been travelled before, but not by persons in search of and qualified to obtain geographical information, except in very small part. The explorations of the Krause brothers on the Chilkat and vicinity have been alluded to before. The Yukon has been superficially examined by McMurray, Ketchum, Zagoskin, Dall, Whymper, Raymond, Nelson, and others, and a few points have been astronomically determined; but nothing like an exact map has been attempted, nor do the data for it exist. Astronomical and magnetic observations anywhere along its banks, and especially any data for a map of the Lewis River and its feeders (which are only known from the reports of prospectors and natives), would be of the highest interest.

AT last news has again been received by Dr. Schweinfurth from the well-known African explorer, Dr. W. Junker. He was still in the Nyam Nyam country, and his last news was dated October 16, 1882, from the residence of a chief named Semio some days' journey south of the Mosio district of the present maps. Dr. Junker, who has travelled through vast districts hitherto unexplored, will now soon return home. The last time he had spent principally in various excursions, during which he repeatedly crossed the Uëlle River to the south, and also the third degree north latitude, leaving his provisions in the care of his companion, Herr Bohndorff. On September 27 he again joined the latter after an absence of eighteen months, but found him so poorly that he had to send him home with the collections made up to that time. Bohndorff started with thirty-two porters, who carried the natural history and ethnographical collections. Of special interest for geographers was an excursion of Dr. Junker's, which he made south of the former Munsa district of the Monbuttu. Some seven days' journey (about 60 kilometres) south of this place he reached a large river named the Nepoko, which the traveller identified with Stanley's Aruwimi, one of the main northern tributaries of the Congo in the middle course of the latter.

DR. POGGE has sent a report from the Mukenge station on the Lulua regarding his return journey from Nyangwe, showing that this was not quite as peaceable as the journey to Nyangwe, and that he had frequently to defend himself seriously against the enmity of the natives. From the Lualaba to the Lomani, Dr. Pogge travelled by the same route as he had previously come with Lieut. Wissmann

ONE of the most recent additions to the "Bibliothèque d'Aventures et de Voyages" published by Dreyfous of Paris is a volume containing the letters and journals of La Perouse during his famous voyage round the world in 1785–88, which ended in the disappearance of the circumnavigator among the islands of the South Pacific. The volume is annotated by M. George Mantoux, who also supplies a prefatory memoir of the great sailor.

"IM Reiche des Æolus" is the title of a little book by Adolf von Pereira, published by Hartleben of Vienna, and containing reminiscences of a tour the author undertook to the Lipari Isles. It is profusely illustrated and contains a map.

AUSTRIAN papers report that a mountain in the neighbourhood of Czernowitz, in the Bukovina, is manifesting singular symptoms of disturbance. The ground around its base, to the extent of over 1000 fathoms, has opened out in wide and deep chasms. Most of the houses of a village on the spot (Kuczumare) have fallen down.

THE Thuringian Geographical Society met at Jena on the 17th inst., when Prof. Hæckel read a paper on the flora of Ceylon, and Herr G. Kurze one on the outposts of European civilisation on the way from Zanzibar to Lake Tanganyika.

THE SPECTRUM OF THE AURORA

IN view of the increased frequency of auroras, an inquiry into the present position of our knowledge as to their spectra has seemed to me desirable.

The accompanying table gives in wave-lengths all the observations I could find of the position of the bright lines of the auroral spectrum. J. R. Capron's "Auroræ and their Spectra," goes more fully into the subject than any other work I know, and therefore many of the positions are taken from it, being found on the page or plate indicated in the column headed "Page, &c." The authorities for other observations are given in the notes, but in other cases again I cannot now state whence I obtained them.

They are arranged approximately in order of accuracy,[1] but this is manifestly a very difficult matter to decide: if, as is very likely, I have made mistakes in this respect, I hope I shall be excused. I have gone very carefully into the matter, judging of the accuracy of the observations partly by their internal evidence, and partly by the weights which are in some cases attached to them by the observers themselves. The observers' probable errors are given in the table after the positions of the lines. I consider J. R. Capron has attributed too much accuracy to most of the observations of the auroral spectrum that have hitherto been made; certainly he has to mine. Nearly all the observers have measured the principal line; and, as its position is very well known, the measurements of it are to a considerable extent a guide to the amount of dependence that may be placed on the rest. Of course it may happen to be measured correctly by accident, while the rest are incorrect; but, on the other hand, if it is incorrectly measured, it is not likely that the rest will be correct. It is, therefore, very desirable that observers should measure this line at the same time as they measure any of the others; not necessarily in order to a certain its position, but as an indication of the correctness of the rest; although it does not always happen that all the lines are by any means equally accurate.

The most probable positions of the lines, given at the foot of the table, are derived from the most accurate of the observations of each. Below are indicated the observations which have been used in the calculation in each case, with the weight given to each; for I have not taken the simple average of those used, but have given higher weights to those that seemed the best. The "Probable Error," as given below the "Probable Average," is partly calculated and partly estimated; it seems rather large; perhaps it should not really be so large.

My second series of observations (No. 18 in the table) are not absolute measurements, but only comparisons with α and γ. I have therefore not used them in the calculation of the general averages. This series is most likely affected by constant errors much larger than the probable errors given in the table from calculation. It seems rather curious that the actual errors of my first series (No. 17) are nearly all so much greater than the probable errors; and possibly the same thing may occur in some other cases.

E. B. Kirk's observation (No. 28) (though a very rough one as regards position) is one of the most striking of all; and, being unique, confirmation of it is very desirable. It will be described under the different lines, &c., concerned.

Where I have attached to an observation a Greek letter with a note of interrogation, it means that it is uncertain whether the

[1] But the observations of each observer are placed together, however unequal in accuracy they may be.

line observed was that named at the head of the column. It is not always possible to identify the lines, and, in some cases, my identifications disagree with J. R. Capron's.

This table shows eleven distinct and well-separated lines or bands, the existence of all of which may, in my opinion, be considered proved, all but λ having been seen by two or more observers.

Seven have been seen by numerous observers; I have myself seen them repeatedly, though none of the other four with certainty; but these (θ, ι, κ, and λ) have all been seen by trustworthy observers, and therefore may be accepted, though of course further confirmation would be advantageous.

I shall now consider each line separately.

β is the only line yet seen in the red. It exists in all auroras that are tinged with red, though the spectroscope does not always show it. I have always seen this line most easily with a single prism; but often the slit has to be so wide that it appears merely as a red border to α. In those reddish auroras where I have not been able to detect it, its invisibility is probably due to moonlight or some such cause. There can be no doubt that this line is the cause of the red colour. It varies greatly in brilliancy with reference to α; I have seen it as bright as α, but never brighter.[1] It sometimes exists when no redness is perceptible in the aurora, it being overpowered by the other rays.

α is almost always the brightest line in the spectrum. The only exceptions I have seen were that once β was as bright, and once ϵ brighter (see below). α probably exists in all true auroras. In a few very faint ones I have not been able to see it, perhaps because it has been overpowered by the diffused light of the spectrum, which certainly varies in brightness relatively to the brightness of the lines. Very often when there is no decided aurora, a luminosity overspreads the sky, uniform in all directions, though fading gradually towards the zenith; I have several times seen the line α in its spectrum, but at other times it has been invisible, though the light has appeared equally bright.

α and β are slender lines; it is not clear whether this can be said of any of the other lines or bands.

θ. Wijkander's is the only reliable observation of this line, but Vogel has one not far from the same place, and as he states his position is unreliable, there is no reason to doubt its being the same line. There is more doubt whether Peirce observed the same.

ι was observed both by Wijkander and Parent, and probably by Peirce and Copeland.

ϵ consists of two lines, according to Vogel, which I have called ϵ^1 and ϵ^2; the latter, he says, became very bright whenever β appeared. He is the only observer who describes two lines here (though I have at least once suspected ϵ to be double), and therefore it is difficult to tell which of them other observers have seen, or whether they have seen both combined as one band. In the table I have assumed that the latter has usually been the case, or at least that a band has been seen in this place; possibly this band has been different from either. I have therefore placed the observations which seem to apply to the band, or to the combined lines, in a separate column from those that seem to refer to the individual lines; but the average of the former includes the observations of the latter. Barker and Procter describe a band here; also E. B. Kirk, who, in 1880, August 12, saw it as a band fading towards the violet; but in 1882, August 4, it faded away on both sides, though quite sharp at the edges, and with a pretty narrow slit it was broken up into lines—his impression is there were six or eight; and that the group was broader than the distance between ϵ^1 and ϵ^2. He used one of Browning's "Maclean star spectroscopes," with an ordinary convex lens instead of the cylindrical one.

I have carefully examined my observations of this band, to see whether it has appeared more refrangible when the red line has been visible or bright than when there has been little or no red; but the result of this examination is inconclusive. However, in 1869, April 16, and 1874, October 3, I noted that ϵ was relatively brighter in the red part of the aurora than elsewhere, so far confirming Dr. Vogel.

ϵ exists in nearly all auroras that are bright enough to show any line besides α; perhaps in all. It varies very much in brightness with respect to the other lines. I have sometimes found it the brightest next to α, and once the brightest of all, viz. in 1882, November 20, between 5.50 and 6.5 a.m. There was twilight at the time in addition to the aurora, but I do not see how this could produce the effect. Between 5.40 and 5.50 that morning I estimated α three times as bright as ϵ, which was the second brightest line; but I see no way of avoiding the conclusion that it was the brightest of all a few minutes later.

[1] In considering the relative brightness of the different bands, it must be borne in mind that it varies considerably with the width of the slit, the dispersion, &c.

ζ may be seen in most bright auroras. It is sometimes brighter than ϵ.

η is much more seldom visible; but I have several times seen it brighter than either ϵ or ζ; rarely as bright as γ, or brighter than it; but never so conspicuous as it, as the latter is rendered more visible by its position at the edge of the brighter part of the continuous spectrum.

γ and δ belong, I believe, to all auroras, always being visible when the spectrum is moderately bright. But their brightness varies with respect to each other and to α; indeed I do not know any two auroral lines that always vary together.

γ is usually the brightest line next to α, with my mode of observation. Several observers describe it as a band; Vogel as a double band (if not triple). Capron, on the authority of A. S. Herschel, says it consists of "two lines, the first rather more frequently noted than the second" (the more refrangible). I cannot see that this assertion is borne out by the accompanying table, but if it is correct, the two lines must be about 4700 and 4654. I have several times seen γ as a band fading towards the violet. E. B. Kirk, in 1880, saw it as a band; but in 1882, August 4, resolved it into bright lines—a broader group than ϵ, less distinctly bounded, and with a less bright centre, and containing, he thinks, about twice as many lines.

κ appears to have been noted by two observers; one being Wijkander, who seems very accurate.

δ is invariably fainter than γ to me.

λ. Seen only by Lemström; but he says that in 1871, November 22, he "observed it with certainty three separate times."

The likelihood of the existence of lines in the violet or blue (such as λ or κ) in addition to those commonly seen, is manifest to me from the fact that I have twice seen purple in auroras. The first time was at Sunderland, 1869, May 13, at 10.55 p.m., when for a minute or two there was a large patch of coloured light—deep crimson, exquisite pink, and most lovely pinkish purple, gradually passing into one another. The crimson was the same colour frequently observed; the pink was very different, and far more beautiful. The crimson lasted after the other colours faded. The second time was in Skye, 1872, August 3, about 10.30 p.m., when for two or three minutes there were large patches of a beautiful, but not deep, pinkish purple. I had no time to observe the spectrum in either case. It is manifestly improbable that these colours would be caused by any of the ordinary lines of the spectrum; probably one line in the violet or blue, in combination with the red line, could account for the various tints.

Colours are closely connected with the spectrum; but I cannot say I ever saw any in the aurora, except the purples and pink just referred to, that might not be readily accounted for by the ordinary lines of the spectrum with or without the red line; as the only other decided colours I have seen are red and the usual greenish colour, varying somewhat in intensity and perhaps tint. I have seen other less decided colours; but, considering the extent to which the colours of the aurora might be affected by mist, smoke, twilight, moonlight, &c., and one's judgment by the effect of contrast, I could not say that they certainly belonged to the aurora.

The continuous light of the spectrum always reaches from α to δ; being very faint from γ to δ, rather faint from α to ϵ, and sometimes brighter from ϵ to η or to ζ than beyond. Sometimes when ϵ is too faint to be detected, the abrupt brightening of the continuous spectrum at that point is plainly visible. Kirk, in 1882, on the occasion already mentioned, when the spectroscope was pointed between the streamers, saw the spaces from α to ϵ and from ϵ to γ apparently filled with shifting lines, very numerous and close. Not that the lines really shifted, but their flickering caused them to appear shifting, and possibly also to appear more numerous than they really were. When the spectroscope was pointed on the streamers these lines were obscured by the greater brightness of the rest of the spectrum. I have myself often suspected lines between ϵ and γ, besides ζ and η.

It has been suggested that some of the lines may vary somewhat in position; but there is no evidence yet that the apparent variations are due to anything but errors of observation.

A flickering of the lines has been observed in certain cases; in all probability this occurs with the whole spectrum when the

[1] *Archives des Sciences Physiques et Naturelles*, 1874. [2] Reported by Winlock: *American Journal of Science*, vol. xlviii. [3] *Observatory*, 1880, p. 542; 1882, p. 272.

aurora flashes, though it does not seem to have been remarked. My own observations have all been made with a very wide slit, or, which comes practically to the same thing, with small dispersion. This has been owing to the usual feebleness of the greater part of the spectrum; and many of the other observers have for the same reason also used a wide slit. It may be useful to explain the method by which most of my observations were made, as it seems successful for perceiving the lines and general character of the spectrum, though not for measuring the positions. I have simply used one or two, or in some cases three prisms, usually of Chance's dense flint glass, and for a slit, the space between window-shutters nearly shut, or between two planks placed against the window. I hold the prisms in my hand on a simple stand, not always fixed, but so that they may be easily moved with respect to each other and to the slit, so varying the amount of dispersion. The best results are usually obtained by holding them in the position of almost the greatest deviation possible. Varying the deviation alters the focus. If one plank or shutter is placed rather further forward than the other, the apparent width of the slit is varied at will by simply moving one's head to one side or the other. By these means it is easy to observe all the different features of the spectrum, which require different widths of the slit and degrees of dispersion. A vacuum-tube or other light for comparison may be placed behind the slit, though it is obvious that with small dispersion accurate comparisons cannot be made.

I have made some observations with a Browning's "Miniature Spectroscope," with the diaphragm off, but it gives less light than simple prisms. I have also tried a "half-prism spectroscope," by Hilger, but unsuccessfully; but I find that by taking off the outer lens of the eyepiece and the diaphragm much more light is obtained; I have not, however, had an opportunity of trying this plan yet on an aurora.

The number of nights of aurora on which I have seen each line, between 1871, November 1, and 1883, March 27, is as follows:—

β	α	ϵ	ζ	η	γ	δ
11	83	34	14	7	33	26

On thirteen nights I could not be sure of any line, but on six of these I suspected α, or else there was an abrupt fading away about where α should come. There were other auroras—mostly faint ones—whose spectra I did not observe.

The lines visible in the spectrum often vary in the course of a few minutes, and indeed are not always the same in different parts of the sky at the same time. I have never been able to detect that any particular feature of the spectrum belongs to any particular type or feature of aurora, except that the line β belongs to red auroras.

Dr. Vogel thinks it probable that the auroral spectrum is a modified air-spectrum. The following are the most striking coincidences or approximations between my revised list of auroral lines and Vogel's lists of lines in the spectra of air and its constituents. They are sufficient to make the subject one worthy of consideration; but perhaps this is as much as can as yet be said. There are other approximations to very faint air or gas lines, which he regards as of some importance; but, as the lines in the latter spectra are so numerous, one would naturally expect such coincidences accidentally.

Aurora Spectrum Coincidences.

A. S. Herschel has pointed out the proximity of β to the dark atmospheric band α at 6279.

Sunderland THOS. WILLIAM BACKHOUSE

SCIENCE AT KAZAN[1]

THE Kazan Society of Naturalists, which began its *Memoirs* in 1871 with the remarkable work of M. M. Bogdanoff on the birds and mammals of the black earth region of the basin of the Volga, has continued since to publish a series of most valuable explorations of the region of the lower Ural, Volga, and Siberia. We notice thus in the first eight volumes of its *Memoirs* the researches on earthquakes in Siberia, in Turkestan, and on the Ural, by M. Orloff; several valuable papers on the Geology of the Obschiy Syrt plateau, by M. Sintsoff; of the Government of Vyatka, by M. Krotoff; of the Government of Kazan, by Prof. Stuckenberg; and of the banks of the Kama, by M. Zaitseff; a work on the birds of Caucasus, by M. Bogdanoff; a paper on the Teleostei of the mouth of the Volga, by M. Yakovleff; the history of the development of the *Acipenser sturio*, by M. Zalensky; and mycological researches, by M. Sorokin; several papers on the flora of the Government of Perm, by M. Kryloff; and two papers by M. Levakovsky on the substitution of certain species of plants for others in a given region; as well as several valuable researches into the anthropology of the Bashkirs, Voguls, and Votyaks, by MM. Malieff, Sorokin, and Ostrovsky.

The three last volumes of the *Memoirs*, which we have now before us, contain also many valuable papers. In the department of botany we notice the second part of M. Kryloff's flora of the Government of Perm. It contains a complete list of all Phanerogamæ discovered in this interesting province, which includes the Ural Mountains, completed by special researches into the subarctic and Alpine flora of this region. A map shows pretty well how such plants as the *Viburnus opulus*, the *Cystisus biflorus*, the *Tilia parviflora*, and the cereals are stopped in their extension by the Ural Mountains, reappearing again on their eastern slope; whilst others, like the *Quercus pedunculata*, or the *Acer platanoides*, are stopped in their extension towards the east by the western spurs of the Ural and the lowlands of Siberia, their north-eastern limit meeting nearly together with the south-western limit of extension of the *Pinus cembra*, the *Lonicera cœrulea*, the *Spiræa media*, and *Polygonum viviparum*. The whole list contains 948 Angiospermæ, and 8 Gymnospermæ. The Cryptogamæ are represented by 38 Lycopodiaceæ and 124 Lichens.—Dr. Martianoff publishes valuable materials for the flora of the Minusinsk region in Eastern Siberia, comprising a sketch of its climate (according to five years' meteorological observations by A. Krapotkin) and its physico-geographical characters. The flora of Minusinsk is much varied, as it embodies three separate botanical regions: the Alpine, the forest, and the steppe floras, intermingled with one another. Its general character is that of the Altai region, and out of 777 Phanerogams, no less than 714 are Altaic, whilst only 59 belong to the flora of Eastern Asia. The Alpine flora has but 104 representatives; the forest-flora is the most widely spread, and at the same time the richest; it is represented by 579 species. The steppe flora, which covers nearly one-quarter of the Minusinsk district, and appears sporadically even on the plateaux of the hilly tracts, numbers 315 species. We can only notice here the excellent botanical sketches of separate parts of this "Siberian Italy" which we find in M. Martianoff's work. His list of plants, which contains 760 species of vascular plants, is unusually rich also in lower plants, the number of determined Fungi and Myxomycetes comprising 644 species.—An interesting work which has cost much labour to its author, M. Kryloff, is a description of all drugs—mostly plants—used in the popular pharmacies of the Governments of Kazan and Perm. The list comprises about 200 plants, with a description of their use in popular medicine.

The zoological papers in this volume are but two:—On the innervation of the heart of the *Esox lucius* and *Acipenser ruthenus*, by MM. Kazem-beck and Doguel; and on the ear-labyrinth of the Plagiostomi (*Acipenser ruthenus*, *A. sturio*, and *A. schiffa*), by M. Sizoff. Both papers have appeared also in the *Archiv für microskopische Anatomie*.

Geology is represented by the following papers:—On the upper part of the mottled marls, by Prof. Stuckenberg; on the Permian in the Governments of Kazan and Samara, by A. Zaitseff; and on the geology of the Volga between Nijni-Novgorod and Kazan, by P. Krotoff. The Zechstein appears in the region situated between the Kama, the water-

[1] *Memoirs of the Society of Naturalists at the Kazan University*, vols. ix., x., and xi., 1880-1882.

shed of the Sok and Sheshma, and the Volga, as an island extending from north-east to south-west, and covered on its borders by mottled marls. The former is closely mingled with the latter, as it extends also in the shape of thinner intermediate deposits among the marls; but on the whole it substantially differs from them by its fauna, undoubtedly belonging to the Zechstein. As to the mottled marls, they contain the *Unio umbonatus*, Fisch., the *Estheria* sp. (*Posydonomia minuta*, Bronn.), the *Lingula orientalis*, Golowkinsky, scales of *Acrolepis macroderma*, Eichw., and Calamites. The Post-Pliocene deposits are spread everywhere, and we notice the find of Caspian shells of *Cardium*, together with *Dreissena*, at the sources of the Cheremshan river (left tributary of the Volga, namely, at Balandino, ten miles from the Cheremshanskaya fort). This important find proves thus that the Caspian formerly extended at least as far north as 54° 40′ north latitude. As to the Permian formation to the west of Kazan, M. Krotoff, who includes in this formation both the Zechstein and the mottled marls, calculates that it has a thickness of 810 to 860 feet. Showing further that the fauna of the mottled marls but slightly differs from that of the Zechstein (a complete list of its fossils being given by the author), and that the fossils that are characteristic of these marls (*Unio umbonatus*, Fisch., *Unio castor*, Eichw., *Estheria* sp., *Cythere* sp., remains of fishes, and Calamites) were found elsewhere, either in company with purely Zechstein forms or in deposits subordinate to the Zechstein deposits, he concludes—perhaps too soon—that there is no ground to consider them as Triassic.

Anthropology and archæology are represented by several interesting papers:—M. Krotoff publishes his researches into the age of the stone implements found in the basin of the Oka, and M. Ivanoff on the Perm region.—M. Malieff publishes the results of his most interesting measurements of the Old Bulgarian skulls dug out from the Babiy Bugor, at the Bulgarian village situated on the left bank of the Volga, close to Tetushi, and his paper is accompanied by sixteen photographs of four skulls. He measured the best preserved twenty-five skulls, all belonging to full-grown males. They are all much like one another, but could be subdivided into three groups: fourteen dolichocephalic, with indexes varying from 71·4 to 77·1; five mesatycephalic, their indexes varying from 77·8 to 79·8; and five subbrachicephalic, whose indexes vary from 81·1 to 82·1. The average size of the horizontal circumference of the twenty-five skulls is 515 millimetres, with a maximum of 555 millimetres and a minimum of 490; the average capacity is 1381 cubic centimetres. They completely differ from the skulls of other inhabitants of the same region: not only Kalmuks, or Bashkirs, but also from the Russian, Tartar, or Mordovian skulls. Without expressing a definitive opinion until a comparison of these skulls with those of Bulgarians from the Balkan peninsula is made, the author points out that they are very much like those of the Koorgan inhabitants of the Government of Moscow, who seem to be Old-Sclavonic, and certainly are not Finnish, as results from an inquiry made on 120 skulls by Prof. A. Bogdanoff. They are similar also to the skulls of the old inhabitants of Kieff and to those of the Scythes of Southern Russia. M. Malieff's companion in these researches, who gives in the same periodical a sketch of the Old Bulgarian burying-place at Babiy Bugor, adds that the skeletons they dug out had their heads towards the west, and were lying on the left side, looking towards the north (towards the Volga). Masses of pieces of earthenware were found together with the skeletons, and the pottery was of the roughest kind, made by hand, and burned very incompletely. He argues with much probability that this burying-place did not belong to a Mussulman people, but to idolaters, and supposes that its antiquity may be traced as far back as the Stone period. In any case, the customs of burying, as shown by this burying-place, seem to have been very much like those of the Sclavonians before their conversion. As to the burying-places at Chulpanovka and Ukrech, in the districts of Christopol and Laisher, explored by MM. Malieff and Vysotsky and described by the latter in his second "Anthropological Sketch of the Explorations of the Year 1880," and by M. Malieff in his just-mentioned paper, both explorers agree in considering them as belonging to Chuvashes. The craniological measurements which M. Malieff made on twenty skulls show that six of them belong to the mesatycephalic type, the average cephalic index of which is 74·5, and the others are either dolichocephalic, or belong to women and children, or afford a most pronounced asymmetry, and cannot thus give reliable figures.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE

THE *alumni* and other friends of the University of St. Andrews have been roused to action by the threat (now withdrawn) of its possible dissolution, in consequence of insufficient endowment. An "Appeal" which has just been issued shows that 2700*l*. (in sums of from 100*l*. to 1000*l*.) has been already subscribed towards the better endowment of the Professorial Chairs; and a scheme has been set on foot amongst the younger graduates for the no less essential object of securing the augmentation of the open bursaries. Upwards of 200*l*. (in sums of from 1*l*. to 50*l*.) has been already promised towards this special fund, and an appeal from the Committee appointed for this purpose will shortly be circulated. There is good reason to believe that the withdrawal of the obnoxious clause has been partly occasioned by the practical shape which the defence of the oldest Scottish University has thus assumed.

SCIENTIFIC SERIALS

THE *American Journal of Science*, June, 1883.—On the nature of the induration in the St. Peter's and Potsdam sandstones and in certain Archæan quartzites, in Wisconsin, by R. D. Irving. The author extends the conclusions already arrived at by Sorby in several important respects.—On the existence of a deposit in North-Eastern Montana and North-Western Dakota, that is possibly equivalent with the Green River group, by Charles A. White. The paper embodies a detailed description of the new extinct genus and species of Percidæ occurring in the Dakota rocks, by Prof. E. D. Cope.—On the peculiar concretions occurring in meteoric irons, by J. Lawrence Smith. These concretions are found to contain sulphuret of iron, schreibersite (phosphuret of iron and nickel), graphite, daubréelite, chromite, lawrencite, aragonite.—On mineral vein formation now in progress at Steamboat Springs compared with the same at Sulphur Bank, by Joseph Le Conte.—Observations on the transit of Venus, December 6, 1882, at the Vanderbilt University Observatory, Nashville, Tennessee, by Olin H. Landreth.—On the fauna found at Lime Creek, Iowa, and its relation to other geological fauna, by S. Calvin. A complete catalogue is given of the Lime Creek fauna which are compared with those of the Niagara, Cinderhook, and other Devonian rocks.—Observations on stratified drift in Delaware, by F. D. Chester.—On the western discharge of the flooded Connecticut, or that through the Farmington Valley to New Haven Bay, by James D. Dana.—Results of some experiments made to determine the variations in length of certain bars at the temperature of melting ice, by R. S. Woodward, E. S. Wheeler, A. R. Flint, and W. Voigt. The experiments are chiefly made with zinc and steel bars, and the authors found that zinc is the least reliable metal for the components of a metallic thermometer and standard of length, while steel, copper, and brass do not vary appreciably at any ordinary temperature.—On Scovillite, a new phosphate of didymium, yttrium, and other rare earths, from Salisbury, Connecticut, by George J. Brush and Samuel L. Penfield.

Journal of the Royal Microscopical Society for April, 1883, contains:—On five new Floscules, with a note on Prof. Leidy's genera, Acyclus and Dictyophora, by Dr. C. T. Hudson (Plates 3 and 4).—The President's (Prof. P. M. Duncan) address.—The action of tannin on the cilia of Infusoria, with remarks on the use of a solution of sulphurous oxide in alcohol, by H. J. Waddington.—Summary of recent literature.—Proceedings of the Society.

Journal of the Russian Chemical and Physical Society, vol. xv. fasc. 4.—On solutions, by W. Alexeyeff; being an inquiry into the mutual solutions of liquids, as depending upon temperature. The experiments carried out on aniline, amyl and isobutyl alcohols, phenol, &c., lead to the following conclusions:—The hypothesis of Person as to the liquefaction of bodies before solution is not confirmed. The solubility depends upon the molecular cohesion, and increases as this last becomes feebler. Thus, at the same temperature, more of liquid than of solid salicylic acid is dissolved. The solutions are quite different from chemical compounds, and the liquid mixtures are different from solutions.—On the specific volumes of elements in liquid compounds; second paper, by M. Shalfeyeff. The conclusions of these valuable researches are:—The compounds of the fat series are derived from the uneven-atomic carbon; and those of the

aromatic series from the even-atomic carbon. The specific volume of carbon is C = 21 in the C_nH_{2n} compounds of the former series, and C = 12 in the C_nH_{2n} compounds of the second series.—On Caucasus naphtha, by M. W. Markovnikoff and W. Ogloblin, being a thorough analysis of it.—On the identity $(\Sigma a_i x_i^2)\Sigma a_i = (\Sigma a_i x_i)^2 + \Sigma a_i a_k (x_i - x_k)^2$, and its meaning in physics, by N. Slouguinoff.—On the focal properties of diffraction-nets, by M. Merching.—On the specific properties of indiarubber, by N. Heselius. They cannot be explained by the presence of air vesicles.

To the *Bulletin of the Belgian Académie Royale des Sciences*, for 1883, part 2, M. C. Malaise sends a valuable paper on the constituent elements of the Silurian formations of Brabant. An approximate thickness of 12,000 or 14,000 feet is assigned to the various groups constituting the older schistose rocks of this province.—Ed. Dupont deals with the origin of the Belgian Carboniferous limestones; and papers are contributed by M. Terby on the aspect and positions of the great comet of 1882; by M. Chevron, on the inflammable nature of the gases liberated in the decomposition of beetroot; by Baron Kervyn de Lettenhove, on the Conference of Bayonne of 1565; by Alphonse Wauterson, on the origin and rise of the early Flemish school of painting previous to the Van Eycks.—Part 3 contains contributions by J. de Tilly, on Chasles' theorem of central axes; by Ed. Van Beneden, on some additions to the ichthyological fauna of the Belgian seaboard; by M. Genocchi, on the algebraic functions of Prymand Hermite; by Joan Bohl, on the reforms recently introduced into the commercial jurisprudence of Italy.

Rendiconti of the *Reale Istituto Lombardo di Scienze e Lettere*, April 12, 1883.—Some applications of symbolic variability to mechanical problems, by S. C. C. Formenti. This paper is concluded in the next number, April 26.—On springs, head streams, and underground currents in the Italian Alps, by Prof. T. Taramelli.—Experimental researches on the decomposition of adipose substances in water, in damp earth, damp rooms, and in water charged with 10 per cent. of ammonia, by C. A. Tamassia.—A study of microscopic organisms in sweet, salt, and mineral waters, by Prof. L. Maggi.—Remarks on the equivalence of magnetic and galvanic distributions, by Prof. E. Beltrami.—A preliminary inquiry into Zanardelli's proposed Italian penal code, by Prof. A. Buccellati.—On an unpublished letter of Francesco Maurolico, dated September 11, 1571, in connection with the battle of Lepanto, by L. De-Marchi.—On an example of realism in classic art, by Prof. J. Gentile.

April 26.—A comparative study of the aracnofauna of Abyssinia and Shoa, by Prof. Pietro Pavesi. The author determines thirty new species of spiders, for one of which (*Chiasmopes*) he establishes a new order.—On the determination of the coefficients of specific force for iron independently of Wöhler's numbers, by Prof. C. Clericetti.—Suggestions on a substitute for capital punishment in Zanardelli's new Italian penal code, by Cesare Oliva.—Remarks on banking and the cheque system introduced into the new Italian commercial code, by L. Gallavresi.

Atti of the Roman *Reale Accademia dei Lincei*, April 1.—On Finlay's comet (1882), by S. Respighi.—On the first observer of the optical illusion converting convex into concave and concave into convex surfaces, by S. Govi. The priority of discovery usually assigned either to Joblot (1718) or to Christopher Cock (1688) is here credited to Eustachio Divini (1663) on documentary evidence.—On the presence of native cinnabar and sulphide of silver in the Tolfa Hills, by S. Blaserna.

April 15.—Biographical notice of the late Bertrando Spaventa, by S. Ferri.—On the migrations of the ancient peoples of the Armenian Highlands and Asia Minor, studied in the light of the Egyptian monuments and hieroglyphical inscriptions, by S. Fiorelli.—A notice of the archæological discoveries made in various parts of Italy duriug the month of March, by S. Fiorelli.

Revue internationale des Sciences biologiques for March, 1883, contains:—On the origin of the vertebrates and the principle of the transformation of functions, by Dr. A. Dohrn.—On the excitability of plants, by Dr. Burdon Sanderson.—On dwarfs and giants, by D. L. Delbœuf.—Proceedings of the Academy of Sciences, Paris, of the Belgian Academy, and of the Academy of Amsterdam.

April, 1883, contains:—On the primordial flora, by Louis Crié.—On the origin and relation of sex, by M. Debierre.—On colour and mimicry in insects, by Dr. Hagen.—Proceedings of the Academy of Sciences, Paris, and the Academy of Sciences, Amsterdam.

SOCIETIES AND ACADEMIES

LONDON

Royal Society, May 10.—"Note on the Motor Roots of the Brachial Plexus, and on the Dilator Nerve of the Iris." By David Ferrier, M.D., LL.D., F.R.S., Professor of Forensic Medicine in King's College.

In a communication to the Royal Society (published in the *Proc. Roy. Soc.*, vol. xxxii. 1881) on the "Functional Relations of the Motor Roots of the Brachial and Lumbo-Sacral Plexuses," my colleague Prof. Gerald Yeo and myself gave an account of the results of electrical stimulation of the several motor roots of the brachial and crural plexuses in the monkey. We there described the muscular actions of the upper extremity as resulting from stimulation of the first dorsal up to the fourth cervical nerve.

The careful dissections made at our request by Mr. W. Tyrell Brooks, Demonstrator in the Physiological Laboratory, King's College, and a repetition of the stimulation experiments which I have made, have revealed an error in the enumeration of the roots of the brachial plexus which, in common with Prof. Yeo, I wish to correct. What we took for the first dorsal nerve has proved in reality to be the second dorsal. Hence the results of the experiments must be read as applying to the spinal nerves from the second dorsal to the fifth cervical respectively, instead of from the first dorsal to the fourth cervical, as stated in our paper.

The anterior division of the second dorsal nerve in the monkey apparently invariably gives a well-developed communicating branch to the first dorsal, besides giving off the second intercostal nerve and a branch to the stellate or inferior cervical ganglion of the sympathetic.

The three branches, as seen in a dissection made for me by Mr. Brooks seem pretty equal in size, and all come off from the main trunk together.

The brachial plexis in man is not usually, in text-books of anatomy, considered as deriving any of its component roots below the first dorsal. In "Quain's Anatomy" (ninth edition, p. 619), however, a branch from the second to the first dorsal is given as a variety. On this subject Dr. D. J. Cunningham has published a note in the *Journal of Anatomy and Physiology*, vol. xi. part iii., p. 539, 1877. Dr. Allen Thomson having mentioned to him that he had on one or two occasions seen such a communicating branch in man, he investigated the point, with the result of finding a communicating branch from the second to the first dorsal in twenty-seven out of thirty-seven dissections. Of the ten cases where it was not found, five were so complicated by previous interference in the dissecting-room or by pleuritic adhesions and thickenings, that they may be considered as doubtful. But, even including these, it appears that the second dorsal sends a communicating branch to the first in 73 per cent. of the cases. Hence it should be considered as more than a mere variety. If a perfect homology exists between the roots of the plexus in man and the monkey, the second dorsal root would be the one presiding over the intrinsic muscles of the hand. Presumably in those cases where it is not found, its functions are represented in the first dorsal.

Dilator Nerve of the Iris.—Prof. Yeo and I mentioned in our paper (*sup. cit.*) that in one case in which we directed special attention to the pupil, stimulation of the anterior roots from the first dorsal to the fourth cervical—in reality from the second dorsal to the fifth cervical—caused no change in the pupil, though the movements of the limb occurred with regularity.

I have since investigated this point during the course of another research on which I have been for some time engaged. I have experimented on four monkeys. The animals were thoroughly narcotised with chloroform and kept so during the whole course of the experiments. The posterior roots of the nerves under investigation were cut, and the anterior stimulated within the vertebral canal with a weak induced current from the secondary coil (distant 20 to 15 cm.) of a Du Bois Reymond's magneto-electromotor and one Daniell. As in former experiments, a large flat electrode was placed on the sacrum as a neutral point, the exciting electrode being a hooked needle, by means of which the roots could be easily insulated and separately stimulated.

In the first experiment I failed to obtain dilatation of the pupil from stimulation of the spinal roots from the second dorsal up to the fourth cervical, though the functional activity of the roots was indicated by movements of the limb. In the second I exposed the dorsal roots from the eighth up to the third in-

clusive. Though different strengths of current were tried, no change in the pupil occurred, unless when the current was so strong as to cause diffuse stimulation. In such cases both pupils would occasionally become dilated, as under sensory stimulation in general. The functional activity of the roots under investigation was shown by contraction of the thoracic muscles on the side of stimulation.

In the third experiment, however, results were obtained of such definiteness and uniformity as to indicate almost without further confirmation the origin of the dilator nerve of the iris.

In this experiment the spinal nerves were exposed from the sixth cervical to the eighth dorsal inclusive. The posterior roots were cut on the left side, and the anterior roots stimulated, while the eyes were carefully observed by two assistants—my pupils, Mr. Norvill and Mr. East. Dilatation of the left pupil occurred almost invariably on stimulation of the second dorsal root, whereas no change whatever could be perceived on stimulation of any of the other exposed roots. This was verified over and over again, and the several roots repeatedly compared with each other. The distance of the secondary coil in this experiment ranged from 20 to 18 cm.

Stronger currents not carefully insulated caused dilatation of both pupils wherever the stimulation was applied, an expression only of general sensory stimulation.

After death a careful dissection was made for me by Mr. Brooks, and the effective root, which was marked, proved to be the second dorsal. An examination with a lens showed that the fibres of the posterior root of this nerve had been completely severed.

The results of the third experiment were entirely confirmed by the fourth.

In this I exposed the spinal nerves from the seventh cervical to the fourth dorsal and cut the posterior roots on the left side.

Here again with the utmost uniformity on each stimulation of the second dorsal, the left pupil, and this one only, became widely dilated; whereas stimulation of the other roots was entirely negative in respect to the pupil.

I ascertained in this experiment that a strength of current which would suffice to excite the muscles of the limb or trunk to action would frequently fail to cause any dilatation of the pupil when applied to the second dorsal. Somewhat stronger, but yet barely perceptible on the tongue, the current at once caused the pupil to dilate. Occasionally also if the second root had been stimulated repeatedly the iris failed to respond, probably from mere exhaustion of the nerve.

Circumstances such as these would, I think, account for the absence of the pupil-reaction in my first experiment, and also in the experiment related by Prof. Yeo and myself, where the second dorsal root was really under stimulation.

The general result of these experiments is to show that in the monkey, and presumably also in man, the dilator fibres of the iris contained in the cervical sympathetic are derived from the anterior root of the second dorsal nerve.

Mathematical Society, June 14.—Prof. Henrici, F.R.S., president, in the chair.—Prof. W. Woolsey Johnson, of Annapolis, was admitted into the Society.—Prof. Cayley, F.R.S., spoke on the subject of sever invariants, and Mr. Hammond's recent discovery.—Prof. Sylvester, F.R.S. (who was very cordially welcomed), and Mr. Hammond spoke on the same subject.—Mr. Tucker (Hon. Sec.) read parts of papers by Prof. H. Lamb, on the mutual potential of two lines in space; by Mr. H. M. Jeffery, F.R.S., on bicircular quartics with collinear foci; and made a few remarks on the subject of inverse coordinate curves.

Physical Society, June 9.—Prof. Clifton in the chair.—Dr. Obach described an improved construction of the movable coil of galvanometer for determining currents and E.M.F. in absolute measure. This is a more sensitive, accurate, and powerful instrument than the old form. It is intended for accurate measurements and testing other instruments. The needle of the new form does not dip; and its vibrations are rendered dead beat by an air chamber. The secants of the inclination of the coil are the multipliers of the tangents of the deflections. The coil consists of a single solid rod or band of copper for measuring powerful currents; and on the same ring is a fine coil of German silver wire for measuring E.M.F. No shunt is required, owing to the movability of the coil. Dr. Obach gave figures showing the accuracy of the apparatus, which is very great.—Professors Ayrton and Perry read a paper on the electric resistance of water, being the result of some experiments made by them some time ago. A comparison of the galvanometer and electrometer methods of measuring this resistance was made during the experiments, the results being in favour of the latter, especially with currents of less than 6 volts. When the electrodes or platinum plates in the water were end-on, the resistance was less than when face to face. Mr. Boys thought this curious result might be due to the resistance between the surface of the plates and the water being reduced. In answer to Dr. Coffin, Prof. Ayrton stated that the plates were heated between every two experiments in the blow-pipe. Prof. G. Guthrie remarked that Kohlrausch had found ordinary distilled water to be much more conductive than pure distilled water, which was an insulator, and inquired if Prof. Ayrton chose pure water. The latter replied that as his experiments were to test the merits of the galvanometer and electrometer modes of testing, ordinary distilled water was used. Prof. Jones stated that he found it best to use alternating currents for measuring the liquid resistance of cells, and described a mercury commutator for rapidly reversing the testing current.—Prof. Ayrton then described a lecture apparatus for showing the laws of centrifugal force. A rapidly rotated arm carrying a movable weight springs from the centre of an aneroid chamber filled with mercury. This chamber is on the rotating axle, and as the centrifugal force of the arm pulls out the diaphragm, the mercury falls in the chamber and in a tube opening from it. Prof. Guthrie remarked that the apparatus would serve as a speed counter.—Prof. Perry then read a paper on the kinetic energy of rotating bodies, in which he pointed out the practical drawbacks to the "moment of inertia" calculations, and suggested the use of a new constant (termed for the nonce the "M"). This is the amount of kinetic energy possessed by a rotating body when making one revolution per minute. To find the energy for N revolutions per minute, multiply this by N^2. In the same way the "M" of a machine can be found and used.

PARIS

Academy of Sciences, June 11.—M. E. Blanchard, president, in the chair.—On some properties of a binary form of the eighth order, by F. Brioschi.—On the homogeneity of mathematical formulas, by A. Ledieu.—Four methods of separating gallium from iridium, by M. Lecoq de Boisbaudran.—Process to be adopted in observing the first radicules of the lymphatic system, and in determining whether these radicules communicate or not with the blood capillaries, by E. Sappey. The intimate union of the radicules with the bloodvessels, which had long been assumed on general grounds, is here demonstrated by actual observation.—Researches on rabies, by Paul Gibier. The points examined are (1) the manner of inoculation; (2) transmission of rabies through the mother; (3) the presence of foreign substances in the stomach of the dog in connection with the diagnosis of rabies; (4) attenuation of the virus: (5) the parasites of rabies. The author shows that the canine, like some other kinds of virus, may be attenuated by cold. That hydrophobia is due to a special parasite, although not yet scientifically demonstrated, is rendered highly probable.—Facts and results serving to determine some new properties of sulphate of iron, by M. Rohart.—On the properties of phosphoric glass (the so-called *verre de phosphate de chaux*), by M. Sidot.—M. de Quatrefages presented, on behalf of M. de Lacerda, a memoir on an organism found in the victims of yellow fever, and by him regarded as a fungus. In the accompanying plate are represented the various stages of development of this organism.—On the track of Encke's comet in the years 1871–1881, by M. Backlund.—On a mode of transformation of figures in space, by MM. J. S. and M. N. Vanecek.—On the theory of the binary form of the sixth order, by R. Perrin.—A study of continuous periodical fractions, by E. de Jonquières (continued).—On the reflection of light on the surface of disturbed fluids, by L. Lecornu.—On the variation of the capillary constant of insulating liquid surfaces, such as ether and sulphuret of carbon, in contact with water, under the action of an electromotive force, by M. Krouchkoll.—On the formation of the glycolate of bibasic soda, by M. de Forcrand.—On the hydrates of barytes, by E. J. Maumené. It is shown that barytes makes no exception to the general law of hydrates, with which the numerous results obtained by Fremy, Filhol, Deville, and others, are in harmony.—On the fermentation of bread-stuffs, by V. Marcano.—On the artificial production of barytine, cœlestine, and anhydrite, by A. Gorgeu.—On the origin and process of formation of bauxite and granular iron, by Stan. Meunier.—On respiration in rarefied air, by MM. Fraenkel and Geppert.

June 18.—M. Blanchard, president, in the chair.—A despatch from San Francisco was read announcing M. Janssen's discovery of the Fraunhofer spectrum and of the dark lines of the solar spectrum in the corona, implying the presence of cosmic matter round the sun. Five photographs were taken of the corona and circumsolar regions to a distance of 15° for intra-Mercurial planets.—A new method of determining the right ascensions and absolute declinations of the stars (continued), by M. Lœwy. —On a drawing of the great comet of 1882, executed at M. Bischoffsheim's observatory near Nice, by M. Faye.—On the movements observed in the monolithic pillars supporting the meridian of the Neuchâtel Observatory, by M. Faye. From these observations, which have been regularly recorded since the foundation of the Observatory in 1859, it appears that even the most solid parts of the earth's crust are subject to slight movements, slow, regular, and partly oscillatory; also that the variable intensity of the movements depends on the one hand on the meteorological conditions of the year, while it is connected on the other with the periodical perturbations produced in the solar photosphere.—On a system of optical telegraphy established by M. Adam between the Islands of Mauritius and Réunion, by M. Faie.—On a carbon meteorite which fell on June 30, 1880, near Nogoga, province of Entre-rios, Argentine States, by M. Daubrée.—Experimental and clinical researches on the method of producing anæsthesia in the organic affections of the encephalon, by M. Brown-Séquard.—Numerous experiments made on dogs, rabbits, &c., seem to show that the paralysis caused by an organic affection of one of the various parts of the brain depends scarcely ever, if at all, on the cause usually assigned to it, that is, the loss of function of the part destroyed. —On the determination of the fly-wheels of tool-engines, by M. X. Kretz.—On the sulphurets of phosphorus, by M. Isambert.—On a method of transformation of figures in space, by MM. J. S. and M. N. Vanecek.—On the theory of the binary form of the sixth order, by R. Perrin (continued).—On the continuous reduction of certain quadratic forms, by E. Picard.—On the magnifying power of optical instruments, by M. Monoyer.—Evaporation of sea water in the south of France, and more particularly in the Rhone delta, by M. Dieulafait. From various observations the author concludes that throughout the deltaic region, even to a distance of twelve miles inland, the mean annual evaporation of the sea water is at least 6 mm. every twenty-four hours.—On some properties of the sulphuret, selenide, and telluride of tin, by A. Ditte.—Determination of the carbonic acid of the air in the stations selected for observing the transit of Venus, by MM. A. Muntz and E. Aubin.—Volumetric quantitative analysis of sulphuret of carbon in sulphocarbonates, by E. Falières.—On the emetics of mucic acid, by D. Klein.—On the respiratory organs in the Chelonia, by L. Charbonnet Salle. —On the cellules of the follicule in the ovum, and on the nature of sexuality, by A. Sabatier. From his protracted studies of the processes of gemmation and parthenogenesis, the author concludes that in the reproductive elements there are two principles of opposed polarities, the centripetal (blastophore) and centrifugal (spermatoblast). When the two polarities are in a reciprocal state of equilibrium the cellule is in a state of *sexual neutrality*, and capable of parthenogenesis. But should the equilibrium become disturbed by the disappearance of either element through any biological change, one of the elements becomes predominant and the cellule acquires a determined sexuality, male by the elimination of the centrifugal, female by that of the centripetal element. There may thus be various degrees of sexuality, which become completely differentiated only through successive processes of elimination.—New method of discolouration of the pigment in the eye of Arthropods, by C. E. della Torre.—Observations on the movements of the ground in the Chiloë Archipelago, by Ph. Germain.

BERLIN

Physiological Society, June 1.—Prof. Kronecker reported that in a demonstration of the action of the cooling down of nerves upon their conductibility, he observed a lesser velocity of conduction of the stimulus instead of the greater velocity that he expected, and that he had found this observation confirmed by subsequent experiments. Hence the correctness of an earlier casual observation of Herr von Helmholtz, that the cooling down of a nerve diminished its conductibility, which had been denied by subsequent observers, has been vindicated; but Prof. Kronecker admits that the contrary may also be true, because frogs may present, under different conditions and at different seasons, utterly diverse phenomena. The influence of temperature on the excitability of sensory nerves, the complement of the above observation, was investigated in frogs whose spinal cord was cut through by measuring the length of time occupied by reflex movements when their legs were dipped into dilute sulphuric acid (·5 or 1 per thousand) at different temperatures. In the case of all frogs and at all active degrees of concentration of the acid, the time required for the reflex action was shortest, *i.e.* the immersed leg was quickest drawn out, when the acid was coldest—0° or +4° up to +6°—and the time required for the reflex action was on the contrary longer at the temperature of the air of the room, and longest at the highest temperature that was employed, 30° to 35°. The influence of cooling down, not the peripheral nerves, but the spinal cord itself, will be investigated in future experiments.—Prof. du Bois Reymond communicated a short notice from a letter of Prof. Babuchin's to him, which contains a fact interesting as showing the power of adaptation to their surroundings that electric fish possess. Prof. du Bois Reymond had previously called attention to the fact that the electric eels and malapterurus that live in badly-conducting fresh water show, in as far as they have accommodated themselves to this medium, a considerable development of their electric organ in length compared with the small size of its transverse diameter, whereas in the electric rays that live in sea water, which is a good conductor, the electric organ has a greater transverse development; consequently the electromotor powers of the electric organs of the electric eel and malapterurus on one side, and of the electric ray on the other, were to one another inversely as the conductibility of the surrounding media. The measurements of Humboldt and of Sachs of growing electric eels had shown that in their growth the electric organ increased proportionately more in length than in transverse diameter, which is a teleological adaptation to the badly-conducting fresh water. Now the above-mentioned note of Prof. Babuchin contained the communication that in growing electric rays the electric organ increased proportionately much more in breadth than in height; this is likewise in conformity with the adaptation to the sea water, which is a good conductor.

THURSDAY, JULY 5, 1883

WILLIAM SPOTTISWOODE

ENGLISH science is still staggering under the blow it received last week in the death of the universally respected President of its leading scientific society. The world is always the poorer for the sudden withdrawal from its many activities of a man *sans peur et sans reproche*, but there is always an inner world where the loss is more keenly felt, and in this case it is the turn of the world of science to mourn one who has made her name so honoured while he has made his own so loved. It is not too much to say that the death of William Spottiswoode is felt as a personal loss by every real student of any department of natural knowledge who ever came within his influence or had the opportunity of knowing anything of the pure and earnest nature of the man. As is but natural, those who have been working along those lines of thought—and they are many—which he had made or almost made his own, will feel the loss most keenly, not merely because the so precious sympathy is gone, but because of the swift insight, valuable criticisms, and happy suggestions as to future work always so freely at the disposal of any one who would consult him either in difficulties or success.

We should however entirely fail in our duty and in our estimate of what he has done for science did we lay too great stress either upon the special work which he did himself or that which he in a greater or less degree influenced in the manner we have just indicated. How much he has personally done we stated some little time ago, little thinking, alas! that what we gave as the results he had achieved and the honours which had followed upon them was anything more than an earnest of what was to follow. It has proved to be the full tale, but it is still one which places him high in the ranks of scientific workers. But, as we have said, high as his place in science would be from this point of view, we doubt whether it is on that that the greatest stress must be laid.

Some men of science of first class working power are so constituted that the less interest they take in the general conduct of affairs connected with science or scientific bodies the better. A man of this kind helps the affairs on very little and he loses his own time. Spottiswoode was exactly the opposite of such a man. In council every word he uttered was pure gold, and when we remember that it is now twenty-two years since he began his council work as Treasurer of the British Association, and that it has never been interrupted till the time of his death, we get an idea of his influence on our national scientific activity. No effort was too great for him, no time spent too long, no margin of time too short, if anything worth doing had to be done; the personal force and the personal example were both there; dullards became enthusiasts if doing was in question, while enthusiasts were checked at times when action was impolitic or premature.

It can easily be imagined that so cultured a man with such qualities as those to which we have referred was a large figure in other than scientific activities; and that both on the ground of his own personal merit, and as representing the Royal Society as its President, he was a marked figure in our English society.

Hence it is that the movement in consequence of which his remains are being buried in Westminster Abbey to-day was one not at all confined to the scientific world, nor was the claim embodied in the memorial to the Dean of Westminster made simply on scientific grounds. As remarked in the *Times*, "no more distinguished body of men, none more thoroughly representative of the community, ever united for a similar object." When we consider that their names were obtained within two days, the quickness of the sympathy and the unanimity of the feeling indicated among the most prominent and gifted sections of our society were certainly remarkable.

The Dean's letter granting the prayer of the memorialists is one again which does such honour to Spottiswoode that we give it in this place:—

"I am deeply sensible of the loss which the country has sustained in the death of the President of the Royal Society. The names appended to the weighty memorial which you have just laid before me are sufficient evidence of the widespread desire that the highest public honours should be paid to the memory of one whose peculiar claims have been urged so forcibly. In addition to that memorial, I have this morning received one expressing the same desire, and bearing the signatures of many hundreds of working men, with whom he was brought in daily intercourse. Although in consideration of the limited space yet remaining for interment within the Abbey I should have myself suggested a monument rather than a grave, yet I cannot but assent, after much anxious consideration, to the wish that your memorial expresses. I recognise in the late Mr. Spottiswoode, not merely a man of special scientific attainments, but one who from his interest in and sympathy with all the many branches and departments of scientific knowledge was peculiarly fitted to represent English science in its widest aspect, and who was at the moment of his death the chosen and the honoured President of the Royal Society. I recognise in him also a man of the very highest and most stainless character—one whose great gifts were only equalled by the purity and attractiveness, and, I may be allowed to add, the devoutness and humility, of his daily life. And, not least of all, I feel that in honouring him we are not only honouring one whose name is dear to men of science and of literature, and of eminence in every sphere of public and of social life, but one whose memory will long be treasured by the working classes, to whose highest interests and welfare he was so deeply devoted."

William Spottiswoode then is buried in Westminster Abbey to-day, by the side of his ancestor, an Archbishop of St. Andrews'; and his remains will be followed to the grave by representatives of the scientific bodies and other interests with which he was connected; nor will sympathy for the widow be wanting to fill up the cup of sadness. English science sorrows, and will long sorrow for the heavy loss, but still she is the richer for Spottiswoode's life and work, not least because his life was so good and so pure, and because, as President of the Royal Society, he has set an example which whoever succeeds him will be proud to follow.

It must not be forgotten that the Presidency of the Royal Society is the highest honour which it is in the power of the Fellows of that Society to bestow. How worthily and how well it was bestowed in the case of Spottiswoode is patent to all. A great responsibility,

therefore, now rests upon them, for he upon whom their choice falls will not be merely the representative of English science in London, he will represent it on the Continent and in America; the choice must bear the criticism of scientific men in other lands. EDITOR

SIR EDWARD SABINE

SPOTTISWOODE, round whose grave in Westminster Abbey so many men, great in so many ways, have stood to-day, is not the only President of the Royal Society, and not the only man of science whose loss we have to deplore. While one, however, was cut off in the full tide of his life, and while there seemed to be a rich promise of many years of valuable work in store, the other had far outlived his working powers, and by many years exceeded those of his activity.

A reference to the life-work of Sabine will clearly show how justly his high position and reputation were accorded to him, how nobly he has worked in the cause of science, and how imperishable a record of his life remains in the existence of a whole branch of scientific research, the foundation of which was mainly due to his untiring industry.

Coming of an old family said to be of Italian origin, which early settled in Normandy, and removed thence to our own country, Edward Sabine was born in Dublin on October 14, 1788, being the son of Mr. Joseph Sabine of Tewin. He received his early education at the Royal Military Colleges of Marlow and Woolwich, obtaining a commission as second lieutenant when but fifteen years of age, and receiving his captaincy eleven years later.

Very early in life indeed, his interest became centred in physical science, and especially in magnetism, the study of which he pursued with indefatigable zeal and marked success. The result of his work in this and other fields is to be found in the many papers which issued from his pen. In 1818, six years before Spottiswoode was born, he was elected a member of the Royal Society, and in the same year was appointed astronomer to the expedition under the command of Sir John Ross which left England in search of the North-west Passage. The careful observations which he made whilst with the expedition were of great value. His published papers begin from this date, commencing with a contribution to the *Transactions of the Linnean Society*, on the birds of Greenland, the result of observations made during the voyage; they range from that date down to the year 1872, thus extending over a period of no less than fifty-four years.

During this long period of active work he contributed to the *Transactions* and *Proceedings* of various societies and contemporary magazines upwards of one hundred papers, some of great length and many of considerable value and importance. Although a large number of these deals with the subject of terrestrial magnetism, many other branches of science are included in them, the voluminous nature of his published works being not less remarkable than the wide fields of study over which they range.

A considerable number are to be found in the *Philosophical Transactions*, to which he contributed upwards of forty. To the *Proceedings of the Royal Society* he made numerous contributions during his long association with it; in the *Quarterly Journal of Science* he published twelve papers, in the *Reports of the British Association* we find ten, to the *Philosophical Magazine* he made eight contributions, the remainder of his published works being scattered among the *Edinburgh Journal of Science*, *Journal of the Geographical Society*, the *Proceedings* of one or two foreign societies, and the pages of foreign scientific magazines.

As we have already said, his scientific contributions date from his voyage to the Arctic regions with Sir John Ross in 1818. Next year he again went to the Arctic regions, this time with an expedition under the command of Sir Edward Parry. As the result of his observations there, he made two communications to the Royal Society, published in the *Philosophical Transactions*, dealing, the one with the irregularities observed in the direction of the compass needle consequent upon the attraction of the iron of the ships, the other with the variations of the magnetic needle, and the intensity of the magnetic force during the voyage, and calling attention for the first time to the extreme importance of founding a widely extended series of observations of those strange magnetical disturbances, the origin of which is still mysterious. With this object in view he left England two years later on a long voyage in H.M.S. *Pheasant*, making numerous observations and bringing many new facts to light. At the same time at several equatorial stations on the coasts of Africa and America he made observations with regard to the swinging of the pendulum, with the object of determining the true figure of the earth, publishing the results in the *Philosophical Transactions*. When on the American coast during this voyage he took up amongst other subjects the question of deep-sea temperatures, and in the *Philosophical Transactions* for 1823, he at that early period published a paper on the temperature at great depths in the Caribbean Sea, whilst in the same year his busy pen was giving an account of the barometrical measurement of the height of the Sugarloaf Mountain at Sierra Leone, and the Pico Ruivo in the Island of Madeira. Three years later he published in the *Quarterly Journal of Science* an account of the ocean currents met by H.M.S. *Pheasant* during the voyage from Sierra Leone to Bahia, and thence to New York, in which he records that the Amazon stream was crossed at a distance of 300 miles from the mouth of the river. In this year (1823) he proceeded on another voyage, going this time in H.M.S. *Griper* to Norway, Greenland, and Spitzbergen, to continue his magnetical observations, and to extend the series of pendulum experiments. Whilst at the latter place he again took up the question of barometrical measurement of heights, publishing in the *Philosophical Transactions* for 1824 a comparison of that method of measurement with the trigonometrical determinations. Then in the *Edinburgh Journal of Science* in 1825 he dealt with the presence of the Gulf Stream on the coasts of Europe as determined by his observations in the year 1822, and proceeded to discuss the question of depression over the region occupied by the Stream.

In 1826 an account of his magnetical observations at Spitzbergen appeared in *Poggendorff's Annalen*.

Continuing his pendulum swingings in 1827, he set about determining by direct observation the difference in

the lengths of the seconds pendulum at Paris and London. The results of these experiments were published in a paper of some length which appeared in the *Philosophical Transactions* for 1828. At the same time he also experimented with the object of ascertaining the ratio of the magnetic forces acting on a needle horizontally suspended in London and in Paris. In 1829, in the *Philosophical Transactions*, he wrote on the reduction to a vacuum of the vibrations of an invariable pendulum; and in the *Quarterly Journal of Science* for the same year he gave an account of experiments concerning the force of the earth's magnetism, and on the then recent magnetical observations in Siberia of M. Hanstein. In the *Philosophical Transactions* for 1831 he describes some experiments made with the object of determining the length of the seconds pendulum at Greenwich.

For many years from this date he worked mainly at that science on which he had most deeply set his mark, that of terrestrial magnetism. In 1835, in conjunction with Lloyd, Humphrey, and J. C. Ross, he contributed to the *Reports of the British Association* (of which he was an early and active member, filling the post of General Secretary for twenty-one years) an account of the terrestrial magnetic force in Ireland. In the following year he himself published in the *Reports* of that Association an account of the magnetic force in Scotland. As an indication of his range of subjects we may here remark that at this time he published in *Froriep Notizen* a paper concerning the volcanoes of the Sandwich Islands. Then in 1837 we find him again contributing to the *British Association Reports*, this time a paper on magnetic intensity, dealing with the variations it exhibits at different parts of the earth's surface. He also wrote on the same subject two years later in *Froriep Notizen*, *L'Institut*, and *Quetelet's Mathematical Correspondence*. In 1838 a memoir on the magnetic isoclinal and isodynamic lines in the British Isles appeared in the *British Association Reports*, being prepared from observations made by Prof. H. Lloyd, J. Phillips, R. W. Fox, Capt. J. C. Ross, and the indefatigable Sabine. In 1840 he continued his papers on terrestrial magnetism in the *Philosophical Transactions*, now taking for his subject the consideration of lines of equal inclination and intensity in the Atlantic Ocean, and on lines of magnetic intensity between the Cape of Good Hope and Australia. He added to this series in the following year by contributing an account of the observations made by Capt. Belcher on the west coast of America and adjacent islands, and the new determination of magnetic elements at Otaheite. Writing in 1838 Sabine had so conclusively demonstrated the importance of magnetical observations being made in every part of the globe, that Capt. James Ross was sent with the *Erebus* and *Terror* to make a magnetical survey of the Antarctic regions. Sabine of course accompanied the expedition. In extension of the work of the magnetic observatory which he had established in England, and which was carried on entirely by his influence, Sabine had induced the authorities to promote the establishment of observatories in the colonies. On the voyage out, therefore, not only were numerous observations made, but magnetical and meteorological observatories were founded at St. Helena, the Cape, and Van Diemen's Land, thus permitting a great increase in the number of possible observations, and a consequent more rapid advance of the science which Sabine had so much at heart. These observatories —to our disgrace be it said, some have now been abolished —were placed under the superintendence of Sabine, and at this period a general magnetic survey of the globe was commenced by him under the direction of the Admiralty, although from what has gone before it is easy to see that the initiative of such a gigantic task had come from himself.

In 1842 he yet further added to his contributions to terrestrial magnetism, publishing in the *Philosophical Transactions* an account of observations made during the voyage of the *Erebus* and *Terror* from England to the Cape, and from thence to Kerguelen Island. Then in 1843 he wrote concerning the extension of these observations from Kerguelen Island to Van Diemen's Island, giving an account also of the various observations made in the Antarctic circle itself during the summer of 1840 and 1841, adding in the year following (1844) an account of the observations from June, 1841, to August, 1842, in the same region. In 1844 and 1845 he made contributions to the *British Association Reports* concerning the meteorology of Toronto and Bombay. During 1846 he again made contributions to meteorological literature, discussing the winter storms of the United States, and the cause of the mild winters which occur sometimes in our own country.

With reference to the survey of the globe to which we have referred, we find him next giving an account of a magnetic survey of a considerable portion of the North American continent, and of the southern hemisphere between the meridian of 0° and 125° east, and parallels of − 20° and − 70°. In 1849, in another contribution, he gave a map of the magnetic declination for 1840 in the Atlantic Ocean, between the parallels of 60° N. and 60° S. latitude. In this year it was that Humboldt's *Cosmos*, for the author of which Sabine had a profound admiration, began to be issued in England, being translated by Mrs. Sabine, and edited by her husband, it being completed in 1858. In the year following he became vice-president of the Royal Society, with which he had been so long connected.

The colonial observatories were, as we have said, under the control of Sabine, and remained so for many years. In 1851 and 1852, and again in 1856, he continued his papers on the magnetism of the earth.

It had been observed (first by Lamont) that the mean of the larger magnetic disturbances gave signs of being bound by some law, and of having a definite but long-period variation. Previously to this it had been shown by Schwabe that the number of spots on the surface of the sun increased and decreased in obedience to regular law, the cycle occupying nearly eleven years for its completion. The results of the observations at the colonial observatories led Sabine to the discovery that magnetical disturbances were intimately bound up with this solar spot period; that the connection between them was of such a nature, that a year of large declination coincided with a year of maximum sunspots, whereas those years when the range in declination was small corresponded with years when there were but few spots on the sun. In the same year the same fact was independently determined by Dr. Rudolf Wolf and M. Gautier.

In 1853, at the meeting of the British Association at Belfast, Sabine occupied the presidential chair. In this year he turned to a consideration of the moon's influence on terrestrial magnetism, writing concerning the effect of that body on the magnetic declination at Toronto, St. Helena, and Hobarton ; and taking up the subject again in 1856, he then discussed the lunar diurnal variation at Toronto. At a later period, in the *Proceedings of the Royal Society*, he contributed a paper on the lunar diurnal magnetic declination obtained from the Kew photograms. In 1857 he made another contribution to the *British Association Reports*, discussing the amount and frequency of the magnetic disturbances and of the aurora at Point Barrow, on the shores of the Polar Sea. In the *Philosophical Transactions* for the same year he discussed the question of the existence of the decennial period in the solar diurnal magnetic variations and its non-existence in the lunar diurnal variation of the declination at Hobarton, as M. Kreil seemed to think was the case. He then stated, as the result of a re-examination of the question by the light thrown upon it by the Hobarton observations, that he was as entirely convinced of the existence of this period in the former case as he was convinced of its non-existence in the latter.

Continuing the investigation of this subject, he contributed to the *Royal Society Proceedings* for 1859-60 a paper on the solar diurnal variation of the declination at Pekin. In the same volume of the *Royal Society Proceedings* he also wrote concerning the laws of the phenomena of the larger disturbances of the magnetical declination at Kew Observatory. In 1861, at the request of the General Committee of the British Association, he prepared a report on the repetition of the magnetic survey of England. In this year he succeeded Sir Benjamin Brodie in the presidency of the Royal Society, which position he occupied for the next ten years. In the *Philosophical Magazine* for 1862 he entered into a discussion concerning the cosmical origin of terrestrial magnetism. Two years later, both in the *Philosophical Magazine* and the *Proceedings of the Royal Society*, he published a comparison of the most notable disturbances of the declination at Kew and Nertschinsk during 1858 and 1859. During the next few years, notably in 1866 and 1871, records of the magnetical observations at Kew were published by him. The chief work, however, of this period of his life consisted in concluding his contributions to the *Philosophical Transactions* by reports and reductions of the work done during the Antarctic expedition. In a lengthy contribution in 1866 he resumed the discussion and co-ordination of the various observations, continuing and concluding this in another paper, which is to be found in the *Transactions* for 1868. His last contribution appeared in 1872, when he gave a magnetical survey of the North Polar regions to serve as a companion to the survey of the South Polar regions which had already appeared. It was his earnest wish that he might be spared to complete this, but the infirmities of age were then stealing over him, and it is doubtful whether it would ever have appeared had it not been for the able assistance of Captain, now Sir Frederic Evans, the Hydrographer of the Admiralty, assistance which the author gracefully acknowledges in a postscript to the memoir.

From this date the work of Sabine may be said to have ceased. He had resigned the presidency of the Royal Society the previous year, and he now sought to spend the evening of his life in that retirement and rest to which his advanced age and great works so fairly gave him a claim. He had received the Copley Medal of the Royal Society in 1821, and the Royal Medal of the same society in 1849. In 1869 he was made K.C.B. He possessed also the Prussian Order *pour le mérite*, and was either an honorary or corresponding member of many foreign societies. We mention these facts to show that he retired from his active life full of well-earned honours. In 1879 he lost his wife, who for more than half a century was the close companion of his labours. In the history of the Royal Society his name will ever be valued as that of one who, both as member and as President, was ever foremost in guarding its honour and maintaining its dignity, whilst the kindness and courtesy which as President he displayed to all, not excluding the younger members, will be always gratefully remembered.

It is chiefly by his pendulum observations and by his magnetic determinations and reductions that, as may be gathered from what has been said, his name is so well known in science. The degree of accordance which some of the early determinations of the former kind exhibited was so much in advance of what was at that time thought likely, that they were received with incredulity in some quarters. The discussion which Sir George Airy made long ago, in his article on the figure of the earth, published in the "Encyclopædia Metropolitana," of the pendulum observations then available for that purpose, shows how large a share belonged to the labours of Sir Edward (then Captain) Sabine.

His own magnetic observations were marked by his wonted accuracy; and his discussion of the results obtained at the colonial magnetic observatories led to new and unexpected results. The most striking, perhaps, of these was the discovery of the relation between magnetic perturbations and the more or less spotted condition of the sun's surface, to which we have already referred. Dissimilar as are these phenomena, and difficult as it then at least was to imagine any possible cause for a connection between them, subsequent observations have fully confirmed the conclusion at which he arrived, that connected they are, though what the precise nature of the connection may be is still a matter of discussion.

Though from the nature of the case the work was one of compilation rather than of original observation, his determination of the magnetic state of the earth at a particular epoch, with its accompanying maps of the isoclinal, isogonal, and isodynamic lines was most noteworthy. The search for the original authorities and the application of the corrections requisite to render the observed results comparable with one another occupied a long time, and the results, as we have pointed out, appeared in instalments, as the various regions into which as a matter of convenience the earth's surface was divided were successively completed.

The establishment of the colonial observatories, too, was the direct result of his exertions; and his name will go down to posterity as that of the man who more than any other laboured for the proper establishment of the science of terrestrial magnetism, interesting and important

in its scientific aspect, and pregnant with so many benefits to mankind at large.

He was buried on Saturday, his remains being placed beside those of his wife in the family vault at Tewin; the funeral, in accordance with his own wish, being of the simplest character. In addition to the members of his family and private friends, the funeral was attended by the Secretary and Treasurer of the Royal Society, the Hydrographer to the Admiralty, and representatives of the other Government services with which he had been so long connected.

A MINISTER OF PUBLIC INSTRUCTION

WE are a longsuffering, patient people. The call of Luther to those around him to educate their children and make men of them, as well as provide them with arms—a call at once answered in Germany—is only just now being answered among ourselves.

One of the most beautiful and one of the most touching sights in London now, and one which in our view is a standing disgrace to the politicians who have held sway during the last hundred years, is the gradual rising above dingy roofs and millions of chimneys of the red brick Board schools. The children in London at all events are now being educated, and our future masters are receiving the first rudiments of their instruction, and this much more on account of the intention of their fathers to have it for them, than on account of any farseeing policy of those who are popularly supposed to look in any and every direction for anything that may conduce to the well-being of our country. We have at last got a public instruction, and it is already in the air that that instruction will in time be as free as it is now compulsory. It is a heartbreaking thing to look back and think what might have been had these all too recently built schools overtopped the squalid dwellings of the poor a century ago. How much less squalid those dwellings would be now. The monumental and extensive prisons would probably be less occupied in their every cell than they are now, but the well-being of the country, the output of the country would have been greater, and the struggle with penury, and dirt, and crime would have been less.

This is only one aspect of education, but yet it seems that in this country at all events it is the mainspring of public opinion with regard to the general question. The cry—on many grounds the mistaken cry—for technical instruction has grown from the work of the Board schools, it has gone along the same line at a higher level, and it will go on still further. The enormous development of the Government Science and Art Classes will also go on, and to the credit of the late Sir Henry Cole be it said here that he was wiser than the politicians, and his clear sight and singlemindedness influenced the head of the department with which he was connected, so that the quiet, slow work in science and art began in 1851, long before the present notions of the importance of education really began to take root in our land.

Now that compulsory education is in our midst, now that the importance of science and of art to the national industries is universally acknowledged, now that it is recognised that the education of our workmen must no longer be so disgracefully neglected as it has been, it is again suggested that there should be a Minister to look after these matters.

Ten years ago, as it was well put, the Kinderpest was the care of the Government side by side with the Rinderpest. Both were practically on the same level, both were acknowledged to be nuisances, both might require a public department to look after them, and then money would have to be spent. This was quite a sufficient argument with "statesmen" to let things go on in the old harum-scarum way; for the policy of a Government is to keep money in its purse, honestly if it can, but in any case to do so, as if England were a miser, acknowledging no responsibilities, spurning all delights, and wishing to live a sordid life like the burghers, caring only for their dykes and pikes, whom Luther shamed out of their indifference centuries ago.

There has again, this week, been a suggestion made that there should be a Minister of Public Instruction, who should be responsible for the preparedness of the country in this respect, just as the Minister of War is responsible for the preparedness of it in another direction. Sir John Lubbock must be congratulated upon the way in which he brought the motion forward last Friday. It was a mild, pleading story. As long ago as 1856, he pointed out, the late Lord Derby said:—

"It appeared to him well worthy of consideration whether it would not be well to have a Minister, or the head of a department, who should have no other duties to perform, and who should be, in fact, responsible for the education of the people. . . . He had a strong feeling that the institution of a Minister of Instruction was desirable, that the subject should be altogether separated from the Privy Council."

But that did no good. In 1862 there was another resolution put to the House calling on it to affirm that for the education estimates and for the expenditure of all moneys for the promotion of education, science, and art a Minister of the Crown should be responsible to the House. That also did no good. In 1865 a Select Committee was moved for to inquire into the constitution of the Committee of the Council on Education. It was then urged that education and science and art were beginning to be considered of such importance that—

"The great duty of superintending the various branches connected with the Department of Education should be intrusted to some one responsible Minister, some Minister who should be regarded as a State officer of high authority who should have the sole conduct of that department, and be solely responsible."

And that was shelved.

Nine years later, in 1874, the same view was urged, and the present Prime Minister then admitted "that there was much to be said in favour of the general principle that the expenditure of money for the promotion of education in science and in art should be placed under the control of a single responsible Minister." It is true he said this, but he supported the previous question, so that again came to nothing.

Now that education and science are the great things of the day, not only in this but in all countries, England enjoys the proud preeminence of being the only country—civilised country, we know nothing of Timbuctoo—in which there is not a Minister of Public Instruction. It is lamentable, terrible, to read the debate of last Friday,

and to see the way in which the question was discussed. Mr. Gladstone was impressed by the condition of the House at nine o'clock, but it does not appear that he was impressed with anything else; the importance of education, the importance of science, the importance of art, the daily, almost hourly, increasing importance of these things does not seem to have entered into the question. To a large extent it was merely a question of Cabinet convenience and Parliamentary tweedledum and tweedledee. How can there be made room in the Cabinet for a Minister of Public Instruction? Are not the affairs of the Duchy of Lancaster of much greater importance, and would not the recognition of the importance of education make the Cabinet unwieldy and give rise to difficulties in Parliamentary procedure? And then there is the Scotch business that must be looked after first, and so on, and so on. Education is evidently not in the region of practical politics.

Heaven knows changes sufficiently great have been made of late years, and it is not absolutely certain that the fundamental bearings of the nature of the changes to be made have in all cases been fully considered; but it seems as though they are to be most carefully considered before any change is made touching the matter of education.

Still it is acknowledged that the question is, after all, one that deserves the attention of Parliament, but Mr. Gladstone had, as usual, three objections to make. In the first place he expressed very great doubt whether, if he had a plan ready to alter the present arrangement, it would be wise to make any declaration on the subject by way of motion. Secondly, he admitted that there was no plan, and he did not think the time had arrived for one; and lastly, he considered that the subject ought to be a great deal more examined before the House committed itself to a final opinion whether there should be a plan or not.

With reference to his first objection he stated that the House knew perfectly well that administrative changes are made piecemeal, and must continue to be so; and he remarked that there was a good deal to be said in favour of what was called a patched house, because most of us found it the most comfortable sort of house to live in. A Minister of Public Instruction would be a new patch. and as there is patching going on elsewhere he objects to this; and so on and so on.

The argument which he used in favour of the second objection was, we imagine, the strongest he could have used against it, namely, that the business of the Council Office in respect to education has been in an almost incessant state of flux and change. Of this there can be no doubt that the flux and change will get more pronounced as time goes on. That is the very reason why everything should be brought to a focus.

We may gather from Mr. Gladstone's speech that the Universities should ever, in his opinion, remain divorced from the general question of education; but if so, what is to become of Prof. Huxley's ladder from the gutter to the university? We think, too, if Mr. Gladstone had been fully informed on the subject he could have urged as an additional objection that a great many questions referring to education are never now touched by the Education Department at all.

Several of the speeches might, if we had more space at our disposal, be noticed at some length. Still, we think it worth while to cull the following from the speech of Mr. Forster, an old Vice-President of the Committee of the Council on Education:—

"The Committee of the Council for Trade, or Agriculture, or Education meant nothing whatever. Persons might imagine that the Privy Council occasionally met for the transaction of business, but they never did so either in England or Ireland. The Minister for Agriculture was the President of the Committee of the Council on Agriculture, but he greatly doubted whether that Committee ever met, or ever would meet. . . . The real objection (to Sir John Lubbock's proposal) probably was that it was undesirable to make too much of education, that if we were to have a Minister of Education he might be pushing things on too quickly. . . . There might be a fear that under one Minister too much money would be spent. . . . What was complained of now was that there was no really defined responsibility. The man who moved the estimates and did the work was not the head of a department, and he ought to be. The work was done by a Minister who was controlled by another, and the latter was scarcely seen by the public. He did not see why we should continue that Japanese mode of managing affairs."

It is satisfactory to see that the House of Commons is gradually getting into a better position to discuss such questions as these, but we have felt that the main point is, that the head of the Government does not yet consider that the question of education is one of an importance sufficient to be discussed side by side with what in his opinion is the much larger questions of Parliamentary procedure, and the saving of so many pounds, shillings, and pence. It is true a Select Committee has been agreed to, but we fear that after Mr. Gladstone's speech very little will come of it, as has happened before.

It would be ungraceful not to state that the debate brought out in the clearest possible way the valuable services rendered under great difficulties by the present Vice-President of the Committee of the Council on Education, Mr. Mundella.

But the result remains that we are not to have a Minister of Education. There is agricultural business, including the Rinderpest, and other matters, and these are larger questions than that of national education! Therefore national education must wait. As we said before, we are a longsuffering and patient people. There is, however, little doubt that in some political programme of the future this question will find a place; equal electoral districts and the payment of members are not the only things to be cared for. F.R.S.

EVOLUTION AND CREATION

A Few Words on Evolution and Creation; A Thesis maintaining that the World was not made of Matter by the Development of one Potency, but by that of Innumerable Specific Powers. By Henry S. Boase, M.D., F.R.S., &c. (London: John Leng and Co., 1882.)

Notes on Evolution and Christianity. By J. F. Yorke. (London: Kegan Paul, Trench, and Co., 1882.)

THE first of these works is, as may be inferred from its title, a most curious production. The chief aim of its author is that of sustaining the Biblical Cosmology against what he regards as the fallacious inroads of the theory of Evolution. In carrying out his design he

devotes the first part of his book to a general criticism of the Evolution theory, and the second part to a consideration of the first chapters of Genesis, which he regards as justifying his view that the world "was made by the development of innumerable specific powers." Our readers must not suppose from this form of expression that Mr. Boase seeks to develop a system of Polytheism; on the contrary he is a Monotheist of the most orthodox type, and by his "innumerable specific powers" means only the properties with which matter has been endowed by its Creator. This, at least, is the only meaning which we have found ourselves able, after a somewhat hasty perusal of his book, to attach to this term, which constitutes the core of his "thesis." But if this is his meaning we fail to appreciate the speculative importance which he somewhat ostentatiously attaches to his opinions. For the great distinction which he draws between these opinions and those which are held by evolutionists consists, as he says, in their making "no assumption of an unknown matter endowed with an imaginary all-becoming potency." But so far as physical causation is concerned the two statements amount to exactly the same thing; the only difference between them is the old and well-worn distinction between theism and non-theism—viz. as to whether the observed "potencies" of matter are or are not God-endowed. We cannot see that Mr. Boase has contributed anything new to this question, and therefore regard his work as lost labour. There is a simplicity about some of his remarks which appeals to us as almost pathetic. For instance:—"From my point of view, the occurrence of some of the same kinds of organisms in the rocks of adjoining formations may arise from the remains of the older rocks being transported into the newer formations, or from the older organisms being created anew as a part of the more recent series. . . . It may here be noticed that such an alternate destruction and reproduction of living creatures is set forth in the civ. Psalm—'Thou takest away their breath, they die, and return to their dust. Thou sendest forth Thy spirit, they are created; and Thou renewest the face of the earth.' This verbal coincidence is curious, but, of course, cannot be adduced to prove that the doctrine of Creation and science are in accord with one another." If the "point of view" in question is to be thus calmly attributed to "science," the concluding sentence of this passage is one of the very few in the book with which we are able cordially to agree.

Again, speaking of the creation of Eve, our author remarks:—"It may also have served as an occasion for the important lesson, that the Lord God was the Creator of these living creatures (animals), for immediately after this, God gave Adam a practical proof of His power to create a living being." Practical proof, no doubt, but we should have thought almost more startling than could have been justified for the purpose suggested. Seriously, however, the absurdity which such passages as these display might be amusing from the mouth of a street-preacher; from a man of cultivation they are, as we have said, pathetic.

The other work which we have to notice stands in every way at the opposite pole of thinking from the one which we have just considered. For the object of Mr. Yorke is to show that the principles of evolution are alone sufficient, without any hypothesis of supernaturalism, to explain the origin and development of Christianity. The book is, therefore, mainly of an historical character, and although its views cannot fail to be obnoxious to orthodox opinion, the temperate manner in which they are stated ought everywhere to commend the approval of good taste. Moreover, whatever his readers may severally be inclined to think of his arguments, they can scarcely fail to agree that Mr. Yorke has written a highly interesting book. His object being, as already stated, to trace in the antecedents of Christianity the natural causes of its rise and progress, he has given a selection of quotations from the Jewish writings about the time or shortly before the commencement of the Christian era, and also of the Buddhistic writings long before it, in order that a just estimate may be formed of the extent to which the world is indebted to Christ as a moral reformer. In our opinion Mr. Yorke has shown a sound critical judgment in making this estimate. On the one hand, he is careful to sift out all the elements of the moral teaching which were, so to speak, in the air at the time when Christ taught; and, on the other hand, he is equally careful to distinguish the points wherein the "originality of Christ" was shown. Here we meet with what appears to us a more full appreciation of this "originality" than is shown by most of the other and some of the more eminent writers of the same school.

We shall conclude this notice by quoting two brief passages, one to show the high development of moral feeling which obtained among the Jews immediately anterior to the teaching of Christ, and the other to show the degradation of moral feeling which now obtains in the Roman Catholic ministry of the Christian Church.

"Wear mourning for the Egyptians, suppress the prayer of glorification on the seventh day of the Passover. It is the anniversary of the day when your enemies perished in the Red Sea, and God desires not to be glorified because his creatures have been drowned beneath the waves."

In painful contrast to the singular beauty of this passage, our other quotation is selected from several pages in the same strain which are republished by Mr. Yorke from two pamphlets written expressly for children by a Reverend Father, whose name is, with a singular appropriateness, Mr. J. Furniss. As Mr. Yorke remarks, the Rev. Father Furniss evidently feels that in these degenerate days "Hell is not pictured vividly enough for purposes of practical terrorism, and has accordingly done his imaginative best to supply this great want. And he deserves every credit for his work, for anything better calculated to drive a sensitive child mad with fright it would be impossible to conceive."

After describing the "*Dress of Fire*," and the "*Red-hot Floor*," in one of which there is represented a girl of eighteen, and in the other a girl of sixteen with the Devil taunting their agonies, "The Sight of Hell" goes on to describe—

"'*The Red-hot Oven.*'—See! it is a pitiful sight. The little child is in this red-hot oven. Hear how it screams to come out. See how it turns and twists itself about in the fire. It beats its head against the roof of the oven. It stamps its little feet upon the floor of the oven. You can see on the face of this little child what you see on the face of all in Hell—despair, desperate and horrible."

The only corrective of immoral publications of this description is to be found in reproducing them before public opinion of another kind from that of the unfortunates whose eyes alone they are intended to meet; and it is partly this consideration that has led us to review Mr. Yorke's essay, which, although excellent in itself, is hardly in close enough contact with natural science to demand notice in these pages.

GEORGE J. ROMANES

OUR BOOK SHELF

Iconographie der schalentragenden europäischen Meeresconchylien. Von Dr. W. Kobelt. 4to. Heft 1. (Cassel: Theodor Fischer, 1883.)

THE object of this work is to supply a want which is continually felt by conchologists, and it deserves the greatest success. Dr. Kobelt is well known to science as the editor of the *Jahrbucher* and *Nachrichtsblatt der deutschen Malakozoologischen Gesellschaft*, which has now been published for between fifteen and sixteen years, and as one of the editors of the new *Conchylien-Cabinet* of Martini and Chemnitz; and he is also the author of several works and papers on conchological subjects. It appears from the prospectus of the present work that its scope will be confined to the coasts of Europe, including the English Isles, the Faroes, and Scotland, and bounded by the north coast of Africa, but excluding not only tropical and subtropical species of Mollusca, but those Arctic species from Spitzbergen and the north of Iceland which are not found on the coasts of Upper Norway. This scope, although extensive, is not very definite; and it scarcely accords with our usual notion of the European seas. We do not know what may be the author's limit of depth, whether it is the line of soundings or 100 fathoms; nor whether he will even take the Mollusca now about to be published from the *Triton* cruise between the Faroes and Scotland. The expeditions of the *Josephine*, *Lightning*, *Porcupine*, *Challenger*, *Vöringen*, *Travailleur*, *Washington*, *Knight Errant*, and several others, have of late years done much to aid in the exploration of the European seas at various depths; and the number of species thereby added to the Mollusca has been very considerable and is still increasing. Some additions have likewise been made from time to time to the Mediterranean Mollusca, especially by myself during the present month. Taking into account all these discoveries, I am inclined to reckon the number of species hitherto described as inhabiting the littoral zone and moderate depths in the European seas as not less than 1000; probably 1200 would be nearer the mark.

The first part of the present work, which has now appeared, gives figures of four species only and their varieties, one of which species (*Murex gibbosus*) is Senegalese, and has never (to the best of my knowledge and belief) been found in any part of the European seas. This reduces the number of figured species to 3. Perhaps the species will not be so profusely illustrated in the next and following parts. The published prospectus does not give any idea of the extent of the work. But assuming even that twenty species (large and small) may on an average be figured in each part, the entire work would take not less than from fifty to sixty parts, and would cost for an uncoloured copy 10*l*. to 12*l*., and for a coloured copy 15*l*. to 18*l*. If all the species known to inhabit the European seas, including the abyssal and benthal zones, are to be figured—and I think this ought to be done—the extent and cost of the publication must be increased by probably a fourth more.

However, such calculations have doubtless been considered by the author or his publisher. The work will assuredly be far more scientific and valuable than the very irregular but expensive *Conchologia Iconica* of the late Mr. Reeve, and be not merely an "ouvrage de luxe."

The family *Muricidæ*, which is the first selected for publication, does not seem to be placed in the usual order of classification. All the figures are admirable. The descriptions are in Latin, the text in German. The geographical, hydrographical, and geological distribution, as well as the odontophore and synonymy, are carefully worked out.

J. GWYN JEFFREYS

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*

[*The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to insure the appearance even of communications containing interesting and novel facts.*]

Sand

I HAVE recently been favoured with a reprint of Mr. J. G. Waller's paper upon sand, read before the Quekett Microscopical Society. The subject is so full of interest that I trust I may be allowed to give it a wider publicity in your columns. To render the study of practical use to geologists and physicists, the first step appears to me to ascertain whether it is possible to distinguish with certainty, by aid of the microscope, sand that has been worn by action of wind from sand that has been for long exposed to surf, and this again from sand brought down by torrents. The degree of rounding and the average size of the grains would be, I presume, among the chief characteristics, and it is to be hoped that naturalists abroad will kindly forward examples of undoubted blown and torrential sand, so that this point at least may be settled.

If it should prove that the origin of sand can be pronounced upon with any degree of certainty, from a microscopical examination, we should come into possession of a most valuable aid to the study of at least Tertiary geology. It is well known that marine and freshwater deposits succeed each other repeatedly throughout our Eocene formations, and where deposits of sand are in juxtaposition, it is at present impossible to draw any line between them. It is only possible to surmise that they are of different origin and therefore age, when pebble or oyster beds on the one hand, or films of clay with plant impressions on the other, are accidentally included in them. So far as our own Eocenes go, it appears from Mr. Waller's results that their sands, when of marine origin, possess a percentage of flint grains, but that purely fluviatile sands do not possess any. Marine and freshwater sands are in direct contact in very many of our Eocene sections, and I hope Mr. Waller's researches will enable us to distinguish them and apportion the proper thickness to each.

With regard to the relative rarity of flint-grains and preponderance of quartz, in all the Tertiary and recent sands hitherto examined, it appears just possible that the concussion the flint grains must undergo when beaten for ages in the surf, might induce a molecular change from the colloid to crystalline state, but in the absence of any fact or argument to support such a theory it cannot be seriously entertained. It is however possible that quartz grains reach a final state of subdivision, and then suffer relatively little by attrition, and are therefore almost indestructible, while flint grains become rapidly degraded into mud. This appears to be very much the opinion Mr. Waller has formed. It does seem at first sight matter for surprise that the grinding of flint should not more largely affect the composition of our sea sand; but we must on the other hand reflect on the indestructible nature of the quartz grains that chiefly compose it, that it may have been accumulating since palæozoic times, and the enormous bulk of the quartzose rocks that must have been ground down to supply it during such vast ages, and then compare the sources with flints which in comparison only appeared yesterday, and then but as scattered segregations in a limited portion of a single formation. Flints and flint beaches, recent and ancient, are at our gates, and are continuously renewed by the wearing away of the chalk of which so much of our part of England is composed, and their aggregate mass therefore astounds us; but they after all occur over only a

limited area, and mostly in unconsolidated beds, and it is quite probable that they would not outlast the destructive influences to which they are subjected if these were continued throughout a geological period. The coast-line occupied by flint-shingle is almost limited to portions of Western Europe, and is relatively insignificant. J. S. GARDNER

The Great Comet *b* 1882

M. RAOUL GAUTIER, of Geneva, has recently published, in *Astronomische Nachrichten*, No. 2519, three sets of elements of this comet, calculated from a few observations before perihelion. He says that, as it is possible to represent with the same curve, either a parabola or an ellipse, the nearest observations before and after perihelion, he believes "que si la comète a subi une perturbation dans son mouvement lorsqu'elle a passé à son périhélie, cette perturbation a dû être insensible."

As I am not so far advanced with my calculations, for I have begun a thorough discussion of the movement of that comet, I do not know whether there has been or not any considerable perturbation during the passage near the sun; but can the simple fact alluded to by M. Gautier give us much information on that point?

In fact, we can easily understand that although the orbit after perihelion might be quite different from the orbit before that point, still the positions of the comet at a short distance from perihelion may be pretty well represented, within the limits of the errors of observations, by a single curve, which of course will be of second order, but which will not certainly give the calculated positions of the comet at a certain distance from perihelion agreeing with the observations. If we could prove that the orbits calculated, for instance, from observations between September 7 and 12 and between the 22nd and the 30th of the same month agree together, and give the positions of the comet immediately before and after perihelion according to the observations, then we could say that the movement of the comet was not perturbated during the passage near the sun. But this fact is not proved at all, and instead it seems that the passage through the corona has had some effect upon the movement of that remarkable comet. E. RISTORI

13, Pembridge Crescent, Bayswater, June 16

THIS comet was visible here with the naked eye up to February 28. I so saw it myself on the evening of that day. Owing partly to cloudy weather, partly to moonlight, I had not seen it for ten days or a fortnight previously, but found it on that evening with little difficulty and without any optical help. In my telescope (4-in.) it appeared, roughly, like a long, flat-sided, oval nebula, the central part of the major axis being the brightest of the whole. Two cloudy evenings intervened, and on the following night (March 3) I could not see it with the naked eye, even after finding it with the telescope and knowing exactly where to look, and though the optical condition of the air seemed the same. During April I saw it, with the same telescope, on sixteen evenings, cloudy weather and moonlight interfering on the others. In the present month (May) I saw it five times, that is, up to the 6th certainly, and I believe I saw it on the 9th, but decreasing visibility and increasing moonlight prevented verification. I have just received a somewhat larger instrument (5-in.), with which after the moon has passed I hope to see it again. A. S. ATKINSON

Nelson, N.Z., May 19

Sun Pillar seen in Jamaica

AT sunset on May 15 I saw for the first time in my life the phenomenon called the *Sun Pillar*. A few days later the mail-packet arrived from England, and in NATURE I found much correspondence on its appearance on April 6 at several places in England and Wales between Hull and St. David's.

Major Gibney's admirable description of its general appearance on April 6 (vol. xxvii. p. 605) was so fully confirmed on May 15 in Jamaica that a very brief description may here suffice.

At 6h. 30m. p.m. Kempshot mean time it appeared as a bright ray of light of a faint roseate hue, 2° in width and 30° in height above the horizon, vertical, but not passing through the sun. A rough sketch was made at the time, and the circles of the equatorial were afterwards employed to determine the azimuth of the point where the pillar cut the horizon. This was 70° from the north towards the west; and as the sun's azimuth was 69° at the same time, the pillar passed 1° to the west of the sun. In the sketch the pillar is represented as passing its own breadth to the west of the sun, but as the sun was then just below the horizon the former measure is likely to be more correct.

Now with regard to the nature of the phenomenon, it certainly was not the usual display of the zodiacal light. The light is here seen to perfection; every fine night when there is no moonlight the zodiacal light may be seen following the ecliptic from the one horizon to the other with but little variation, except perhaps as to the *gegenschein* or stronger illumination near the point in the heavens diametrically opposite to the sun. And so clearly is it seen, that some years ago I carefully measured its breadth at different distances from the sun, and so formed the following table:—

Ang. dist. from Sun. °	Breadth of Z.L. °	Ang. dist. from Sun. °	Breadth of Z.L. °
30	41·4	110	20·3
40	38·7	120	17·8
50	36·1	130	15·3
60	33·4	140	13·0
70	30·7	150	10·8
80	28·1	160	8·9
90	25·5	170	7·6
100	22·9	180	7·0

From various considerations based upon the figure corresponding to these measures I consider the zodiacal light a terrestrial phenomenon—rays of light are swept back from the sun, chiefly from the tropical parts of the earth, and tend to accumulate at the point in the heavens diametrically opposite the sun.

If there be any truth in this theory, the sun pillar may be a strong and comparatively local development of the same light; this is the only explanation I can give; the explanation given by Mr. G. J. Symons, the well known meteorologist, "that it is merely a portion of a halo passing through the sun" (vol. xxviii. p. 7), will not apply to the Jamaica observation at all; the sky was far too pure and transparent at the time, and there was not the least trace of *cirrus* cloud. MAXWELL HALL

Kempshot Observatory, Jamaica, June 7

Error in Hutton's Tables of Logarithms

AT the end of Hutton's "Mathematical Tables" (new edition, 1858, Longmans and Co., London) there is a very useful table containing the logarithms of certain constants frequently used in calculation. The tropical revolution of the earth in days is there given as 365·24226, and the logarithm of this most important constant is given as 2·5625910 instead of 2·5625810.

I would be glad to know from any of your readers whether there are any other important errors in this edition, especially among those tables of logarithms in frequent use.

Jamaica, June 4 MAXWELL HALL

Palæozoic Sclerotic Plates

IN the course of my researches among the coal shales of Northumberland I discovered two specimens of ossicular rings known as sclerotic plates. The external diameter of one ring is five-eighths of an inch, and the orbital orifice is one-quarter of an inch; this ring of sclerotic plates consists of nine bones arranged as are the eye bones of Ichthyosaurus, Plesiosaurus, and eagles, viz. in tolerably uniform segments. The second specimen is a quadrant of a ring, and consists of six plates of larger size than the other specimen. I shall be glad to learn if any of your readers have discovered similar sclerotic plates in the Palæozoic rocks of the British Isles, as specimens are not exhibited in the British Museum, Jermyn Street Museum, or Edinburgh Museum. Newcastle-on-Tyne, June 25

Graft-Hybridisation

ST. PAUL, in his Epistle to the Romans, says (ch. xi. v. 17), in illustration of the admission of the Gentiles to the religious privileges of the children of Israel, "If thou, being a wild olive, wert grafted in among them, and didst become partaker with them of the root of the fatness of the olive tree," &c. Olshausen, in his commentary on this epistle, says (English translation, p. 369),

"Whereas, according to the image in this place, the wild branches are ingrafted into the generous tree, reversing the usual process by which good branches are grafted into wild trees, we are informed by both ancient and modern writers that such a process is practicable in this very tree, the olive, and is often practised in the East. Compare Columella 'De Rebus Rusticis,' *v. g.*" Can this be confirmed? It seems scarcely credible. The question bears on the subject of graft-hybridisation, about which many curious facts are collected in Darwin's work on "Variation under Domestication." JOSEPH JOHN MURPHY

Old Forge, Dunmurry, Co. Antrim, June 29

Wild Duck and Railways

LAST autumn I visited Canada and made a journey to the extreme west point (then reached) of the Canada Pacific Railway, on which three or four thousand men were at the time employed laying down the rails on the prairie, at the very rapid rate of three or four miles a day, or more than twenty miles a week. There are many ponds and lakelets along the track, which abounded at that season with a variety of ducks—mallard, teal, widgeon, &c.—usually very shy, and not easily approached by the sportsman. Yet these ducks had in the short space of from two to five days become so accustomed to the noisy and (to most of the birds) novel engine moving along, that they remained sitting quietly in the water within easy shot when the train was passing. On my return journey I was sorry to find that this confidence on the part of the ducks was taken advantage of by the conductor and other wretched sportsmen (?) who shot at the poor birds from the platform of the cars whilst in motion, although when they did *kill*—I am glad to say there were more misses than hits—they could not stop to pick up the game. A sportsman, to get equally near to the ducks as they permitted the train to approach them, had to use the cover of the long grass and some artful dodging to attain his object. This quick intelligence on the part of the ducks seemed to me something remarkable, as the senses both of sight and hearing must have been, one would suppose, at first alarmingly affected by the great noisy, smoking monster rushing along their favourite and hitherto usually silent haunts. JOHN RAE

4, Addison Gardens, June 30

Large Hailstones

A SEVERE thunderstorm passed over Woodlesford, six miles south-east of Leeds, between 3.10 and 4 p.m. this afternoon, proceeding from south-west to north-east. Flashes of lightning during that time were almost continuous. At 3.15 heavy rain began to fall, becoming so thick at 3.25 as to render objects a short distance away almost indistinct; at 3.30 this changed to hail, the stones during the worst period being generally irregular parallelopipeds of ice, with two edges of about one inch each, and the third of one-quarter of an inch. These blocks consisted of hard, colourless, transparent ice, surrounding a central, irregularly-shaped mass of opaque white, small air-bubbles of roughly ellipsoidal shape being ranged round this. The white nucleus was not quite so hard as the exterior transparent coating. The force of collision on the railway line was sufficient to make the masses bound to a vertical height of two or three feet. At 3.45 the hail had moderated, when a few light loose clouds were observed quickly passing from north-east to south-west, and thus directly opposite to the direction of the storm, and at a much lower level. Extinction of Flatfish

I HAVE been advised by Mr. Murray of the *Challenger* expedition to inquire, through your columns, whether the experience of any of your correspondents coincides with mine as to the gradual failure—in some places almost the extinction—of flatfish where whelk-gathering is prosecuted. MALCOLM MCNEILL

The New Club, Edinburgh, June 30

Garfish

IN March last I was being pulled off from the shore to H.M.S. *Himalaya* in the harbour at Aden, when a fish jumped out of the water over the boat, and in doing so struck the hat of another officer and knocked it into the water. When the hat was recovered we found in the *hard* felt a slit about four inches in length. Unfortunately the fish escaped, but the impression of those who saw it was that it was some kind of garfish, and that the damage done was inflicted by the beak. It appeared to me to be about ten inches long. It is obvious that had the fish struck my friend in the face or neck, or even in the chest, it might have resulted in a fatal injury. S. ARCHER

The "Spirogyra quinina"

CAN any of your readers inform me of any practical method of exterminating, in a lodge or reservoir, confervoid algæ, more especially the fine filamentous variety *Spirogyra quinina?*

Hanley, Staffordshire, June 19 FREDK. HAIGH

ACTION OF LIGHT ON INDIARUBBER

IN continuation of the experiments described in NATURE, vol. xxvii. p. 312, two pieces of caoutchouc tube, about 48 mm. long and 7 mm. wide, were introduced on January 23, 1883, into test tubes containing oxygen confined over mercury. One of these tubes was surrounded by a case of black paper, and both tubes were placed side by side in a north window. On June 27 the tubes were examined: in that exposed to light about 17 cc. of oxygen (about three-quarters of the gas the test tube at first contained) had been absorbed, and the india-rubber had become altered, so that on pressing the tube between the fingers superficial cracks were produced. In the other test tube no appreciable diminution of gas had taken place, and the caoutchouc was unchanged, thus fully confirming the results of the former experiments. We may therefore conclude that caoutchouc alters under the combined influence of light and oxygen, but that neither alone produces any effect.

Cooper's Hill, June 29 HERBERT MCLEOD

ON WHALES, PAST AND PRESENT, AND THEIR PROBABLE ORIGIN[1]

II.

THOUGH the early stages by which whalebone has been modified from more simple palate structures are entirely lost to our sight, probably for ever, the conditions in which it now exists in different species of whales, show very marked varieties of progress, from a simple comparatively rudimental and imperfect condition, to what is perhaps the most wonderful example of mechanical adaptation to purpose known in any organic structure. These variations are worth dwelling upon for a few minutes, as they illustrate in an excellent manner the gradual modifications that may take place in an organ, evidently in adaptation to particular requirements, the causation of which can be perfectly explained upon Darwin's principle of natural selection.

In the Rorquals or fin-whales (genus *Balænoptera*), found in almost all seas, and so well known off our own coasts, the largest blades in an animal of 70 feet in length do not exceed 2 feet in length, including their hairy terminations; they are in most species of a pale horn colour, and their structure is coarse and inelastic, separating into thick, stiff fibres, so that they are of no value for the ordinary purposes to which whalebone is applied in the arts. These animals feed on fish of considerable size, from herrings up to cod, and for foraging among shoals of these creatures the construction of their mouth and the structure of their baleen is evidently sufficient. This is the type of the earliest known extinct forms of whales, and it has continued to exist, with several slight modifications, to this day, because it has fulfilled one purpose in the economy of nature. Other purposes for which it was not

[1] Lecture delivered at the Royal Institution on the evening of Friday, May 25, 1883, by Prof. Flower, LL.D., F.R.S., P.Z.S., &c. Concluded from p. 202.

sufficient have been supplied by gradual changes taking place, some of the stages of which are seen in the intermediate conditions still exhibited in the Megaptera, and the Atlantic and Southern Right Whales. Before describing the extreme modifications in the direction of complexity, I may mention, to show the range at present presented in the development of baleen, that there has lately been discovered in the North Pacific a species called by the whalers the Californian Gray Whale (*Rachianectes glaucus*), which shows the opposite extreme of simplicity. The animal is from 30 to 40 feet in length; the baleen blades are only 182 on each side (according to Scammon) and far apart, very short (the longest being from 14 to 16 inches in length), light brown or nearly white in colour, and still more coarse in grain and inelastic than that of the Rorquals. The food of these whales is not yet known with certainty. They have been seen apparently seeking for it along soft bottoms of the sea, and fuci and mussels have been found in their stomachs.

In the Greenland Right Whale of the circumpolar seas, the Bow-head of the American whalers (*Balæna mysticetus*), all the peculiarities which distinguish the head and mouth of the whales from other mammals have attained their greatest development. The head is of enormous size, exceeding one-third of the whole length of the creature. The cavity of the mouth is actually larger than that of the body, thorax and abdomen together. The upper jaw is very narrow, but greatly arched from before backwards, to increase the height of the cavity and allow for the great length of the baleen, the enormous rami of the mandibles are widely separated posteriorly, and have a still further outward sweep before they meet at the symphysis in front, giving the floor of the mouth the shape of an immense spoon. The baleen blades attain the number of 350 or more on each side, and those in the middle of the series have a length of ten or even twelve feet. They are black in colour, fine and highly elastic in texture, and fray out at the inner edge and ends into long delicate, soft, almost silky, but very tough hairs.

How these immensely long blades depending vertically from the palate were packed into a mouth the height of which was scarcely more than half their length, was a mystery not solved until a few years ago. Capt. David Gray of Peterhead, at my request, first gave us a clear idea of the arrangement of the baleen in the Greenland whale, and showed that the purpose of its wonderful elasticity was not primarily at least the benefit of the corset and umbrella makers, but that it was essential for the correct performance of its functions. It may here be mentioned that the modification of the mouth structure of the Right Whale is entirely in relation to its food. It is by this apparatus that it is enabled to avail itself of the minute but highly nutritious crustaceans and pteropods which swarm in immense shoals in the seas it frequents. The large mouth enables it to take in at one time a sufficient quantity of water filled with these small organisms, and the length and delicate structure of the baleen provides an efficient strainer or hair sieve by which the water can be drained off. If the baleen were, as in the Rorquals, short and rigid, and only of the length of the aperture between the upper and lower jaws when the mouth was shut, when the jaws were separated a space would be left beneath it through which the water and the minute particles of food would escape together. But instead of this, the long, slender, brush-like ends of the whalebone blades, when the mouth is closed, fold back, the front ones passing below the hinder ones in a channel lying between the tongue and the bone of the lower jaw. When the mouth is opened their elasticity causes them to straighten out like a bow that is unbent, so that at whatever distance the jaws are separated, the strainer remains in perfect action, filling the whole of the interval. The mechanical perfection of the arrangement is completed by the great development of the lower lip, which rises stiffly above the jaw-bone, and prevents the long, slender, flexible ends of the baleen being carried outwards by the rush of water from the mouth, when its cavity is being diminished by the closure of the jaws and raising of the tongue. The interest and admiration excited by the contemplation of such a beautifully adjusted piece of mechanism is certainly heightened by the knowledge that it has been brought about by the gradual adaptation and perfection of structures common to the whole class of animals to which the whale belongs.

Few points of the structure of whales offer so great a departure from the ordinary mammalian type as the limbs. The fore limbs are reduced to the condition of simple paddles or oars, variously shaped, but always flattened and more or less oval in outline. They are freely movable at the shoulder-joint, where the humerus or upper-arm bone articulates with the shoulder-blade in the usual manner, but beyond this point, except a slight flexibility and elasticity, there is no motion between the different segments. The bones are all there, corresponding in number and general relations with those of the human or any other mammalian arm, but they are flattened out, and their contiguous ends, instead of presenting hinge-like joints, come in contact by flat surfaces, united together by strong ligamentous bands, and all wrapped up in an undivided covering of skin, which allows externally of no sign of the separate and many-jointed fingers seen in the skeleton.

Up to the year 1865 it was generally thought that there was nothing to be found between this bony framework and the covering skin, with its inner layer of blubber, except dense fibrous tissue, with blood-vessels and nerves sufficient to maintain its vitality. Dissecting a large Rorqual, 67 feet in length, upon the beach of Pevensey Bay in that year, I was surprised to find lying upon the bones of the fore-arm well-developed muscles, the red fibres of which reached nearly to the lower end of these bones, ending in strong tendons, passing to, and radiating out on, the palmar surface of the hand. Circumstances then prevented me following out the details of their arrangement and distribution, but not long afterwards Prof. Struthers of Aberdeen had an opportunity of carefully dissecting the fore-limb of another whale of the same species, and he has recorded and figured his observations in the *Journal of Anatomy* for November, 1871. He found on the internal or palmar aspect of the limb three distinct muscles corresponding in attachments to the flexor carpi ulnaris, the flexor profundus digitorum, and the flexor longus pollicis of man, and on the opposite side but one, the extensor communis digitorum.[1] Large as these muscles actually are, yet, compared with the size of the animal, they cannot but be regarded as rudimentary and being attached to bones without regular joints and firmly held together by unyielding tissues, their functions must be reduced almost to nothing. But rudimentary as the muscles of the Fin-whales are, lower stages of degradation of the same structures are found in other members of the group. In some they are indeed present in form, but their muscular structure is gone and they are reduced in most of the toothed whales to mere fibrous bands, scarcely distinguishable from the surrounding tissue which connects the inner surface of the skin with the bone. It is impossible to contemplate these structures without having the conviction forced home that here are the remains of parts once of use to their possessor, now, owing to the complete change of purpose and mode of action of the limb, reduced to a condition of atrophy verging on complete disappearance.

The changes that have taken place in the hind-limbs are even more remarkable. In all known Cetacea (unless

[1] The muscles of the forearm of an allied species, *Balænoptera rostrata*, were described by Macalister in 1868, and Perrin in 1870.

Platanista be really an exception) a pair of slender bones are found suspended a short distance below the vertebral column, but not attached to it, about the part where the body and the tail join. In museum skeletons these bones are often not seen, as, unless special care has been taken in the preparation, they are apt to get lost. They are, however, of much importance and interest, as their relations to surrounding parts show that they are the rudimentary representatives of the pelvic or hip bones, which in other mammals play such an important part in connecting the hind-limbs with the rest of the skeleton. The pelvic arch is thus almost universally present, but of the limb proper there is, as far as is yet known, not a vestige in any of the large group of toothed whales, not even in the great Cachalot or Sperm Whale, although it should be mentioned that it has never been looked for in that animal with any sort of care. With regard to the Whalebone Whales, at least to some of the species, the case is different. In these animals there are found, attached to the outer and lower side of the pelvic bone, other elements, bony or only cartilaginous as the case may be, clearly representing rudiments of the first and in some cases the second segment of the limb, the thigh or femur, and the leg or tibia. In the small *Balænoptera rostrata* a few thin fragments of cartilage, embedded in fibrous tissue attached to the side of the pelvic bone, constitute the most rudimentary possible condition of a hind-limb, and could not be recognised as such but for their analogy with other allied cases. In the large Rorqual, *Balænoptera musculus*, 67 feet long, previously spoken of, I was fortunate enough in 1865 to find attached by fibrous tissue to the side of the pelvic bone (which was sixteen inches in length) a distinct femur, consisting of a nodule of cartilage of a slightly compressed, irregularly oval form, and not quite one inch and a half in length. Other specimens of the same animal dissected by Van Beneden and Prof. Struthers have shown the same; in one case, partial ossification had taken place. In the genus *Megaptera* a similar femur has been described by Eschricht; and the observations of Reinhardt have shown that the Greenland Right Whale (*Balæna mysticetus*) has not only a representative of the femur developed far more completely than in the Rorqual, being from six to eight inches in length and completely ossified, but also a second smaller and more irregularly formed bone, representing the tibia. Our knowledge of these parts in this species has recently been greatly extended by the researches of Dr. Struthers of Aberdeen, who has published in the *Journal of Anatomy* for 1881 a most careful and detailed account of the dissection of several specimens, showing the amount of variation to which these bones (as with most rudimentary structures) are liable in different individuals, and describing for the first time their distinct articulation one with the other by synovial joints and capsular ligaments, and also the most remarkable and unlooked-for presence of muscles passing from one bone to the other, representing the adductors and flexors of mammals with completely developed limbs, but so situated that it is almost impossible to conceive that they can be of any use; the whole limb, such as it is, being buried deep below the surface, where any movement, except of the most limited kind, must be impossible. Indeed, that the movement is very limited and of no particular importance to the animal was shown by the fact that in two out of eleven whales dissected the hip-joint was firmly anchylosed (or fixed by bony union) though without any trace of disease. In the words of Dr. Struthers, "Nothing can be imagined more useless to the animal than rudiments of hind-legs entirely buried beneath the skin of a whale, so that one is inclined to suspect that these structures must admit of some other interpretation. Yet, approaching the inquiry with the most sceptical determination, one cannot help being convinced, as the dissection goes on, that these rudiments really are femur and tibia. The functional point of view fails to account for their presence. Altogether they present for contemplation a most interesting instance of those significant parts, rudimentary structures."

We have here a case in which it is not difficult to answer the question before alluded to, often asked with regard to rudimentary parts, Are they disappearing or are they incipient organs? We can have no hesitation in saying that they are the former. All we know of the origin of limbs shows that they commence as outgrowths upon the surface of the body, and that the first-formed portions are the most distal segments. The limb, as proved by its permanent state in the lowest Vertebrates, and by its embryological condition in higher forms, is at first a mere projection or outward fold of the skin, which, in the course of development, as it becomes of use in moving or supporting the animal, acquires the internal framework which strengthens it and perfects its functions. It would be impossible, on any theory of causation yet known, to conceive of a limb gradually developed from within outwards. On the other hand, its disappearance would naturally take place in the opposite direction; projecting parts which had become useless, being in the way, would, like all the other prominences on the surface of the whales, hair, ears, &c., be removed, while the most internal, offering far less interference with successful carrying on the purposes of life, would be the last to disappear, lingering, as in the case of the Greenland Whale, long enough to reveal their wonderful history to the anatomist who has been fortunate enough to possess the skill and the insight to interpret it.

Time will not allow of more illustrations drawn from the structure of existing Cetacea; we turn next to what the researches of palæontology teach of the past history of the order. Unfortunately this does not at present amount to very much. As is the case with nearly all other orders of mammals, we know nothing of their condition, if they existed, in the mesozoic age. Even in the cretaceous seas, the deposits at the bottom of which are so well adapted to preserve the remains of the creatures which swam in them, not a fragment of any whale or whale-like animal has been found. The earliest Cetaceans of whose organisation we have any good evidence, are the Zeuglodons of the Eocene formations of North America. These were creatures whose structure, as far as we know it, was intermediate between that of the existing suborders of whales, having the elongated nasal bones and anterior position of the nostrils of the Mystacocetes, with the teeth of the Odontocetes, and with some characters more like those of the generalised mammalian type, than of any of the existing forms. In fact *Zeuglodon* is precisely what we might have expected *a priori* an ancestral form of whale to have been. The remarkable smallness of its cerebral cavity, compared with the jaws and the rest of the skull, so different from that of modern Cetaceans, is exactly paralleled in the primitive types of other groups of mammals. The teeth are markedly differentiated in different parts of the series. In the anterior part of both jaws they are simple, conical, or slightly compressed and sharp pointed. The first three of the upper jaw are distinctly implanted in the premaxillary bone, and so may be reckoned as incisors. The tooth which succeeds, or the canine, is also simple and conical, but it does not greatly exceed the others in size. This is followed by five teeth with two distinct roots and compressed pointed crowns, with denticulated cutting edges. It has been thought that there was evidence of a vertical succession of the molar teeth, as in diphyodont mammals, but the proof of this is not quite satisfactory. Unfortunately the structure of the limbs is most imperfectly known. A mutilated humerus has given rise to many conjectures; to some anatomists it appears to indicate freedom of motion at the elbow-joint, while to others its characters seem to be those of the ordinary Cetacea.

Of the structure of the pelvis and hind limb we are at present in ignorance.

From the middle Miocene period fossil Cetacea are abundant, and distinctly divided into the two groups now existing. The Mystacocetes, or Whalebone Whales, of the Miocene seas were, as far as we know now, only *Balænopteræ*, some of which (as the genus *Cetotherium*) were, in the elongated flattened form of the nasal bones, the greater distance between the occipital and frontal bone at the top of the head, and the greater length of the cervical vertebræ, more generalised than any now existing. In the shape of the mandible also, Van Beneden, to whose researches we are chiefly indebted for a knowledge of these forms, discerns some approximation to the Odontocetes. Right Whales (*Balæna*) have not been found earlier than the Pliocene period, and it is interesting to note that instead of the individuals diminishing in bulk as we approach the times we live in, as with many other groups of animals, the contrary has been the case, no known extinct species of whales equalling in size those that are now to be met with in the ocean. The size of whales, as of all other things whose most striking attribute is magnitude, has been greatly exaggerated; but when reduced to the limits of sober fact, the Greenland Right Whale of 50 feet long, the Sperm Whale of 60, and the Great Northern Rorqual (*Balænoptera Sibbaldii*) of 80, exceed all other organic structures known, past or present. Instead of living in an age of degeneracy of physical growth, we are in an age of giants, but it may be at the end of that age. For countless ages impulses from within and the forces of circumstances from without have been gradually shaping the whales into their present wonderful form and gigantic size, but the very perfection of their structure and their magnitude combined, the rich supply of oil protecting their internal parts from cold, the beautiful apparatus of whalebone by which their nutrition is provided for, have been fatal gifts, which, under the sudden revolution produced on the surface of the globe by the development of the wants and arts of civilised man, cannot but lead in a few years to their extinction.

It does not need much foresight to divine the future history of whales, but let us return to the question with which we started, What was their probable origin?

In the first place, the evidence is absolutely conclusive that they were not originally aquatic in habit, but are derived from terrestrial mammals of fairly high organisation, belonging to the placental division of the class,—animals in which a hairy covering was developed, and with sense organs, especially that of smell, adapted for living on land; animals, moreover, with four completely-developed pairs of limbs on the type of the higher vertebrata, and not of that of fishes. Although their teeth are now of the simple homodont and diphyodont type, there is much evidence to show that this has taken place by the process of degradation from a more perfect type, even the fœtal teeth of Whalebone Whales showing signs of differentiation into molars and incisors, and many extinct forms, not only the Zeuglodons, but also true dolphins, as the Squalodons, having a distinct heterodont dentition, the loss of which, though technically called a "degradation," has been a change in conformity to the habits and needs of the individuals. So much may be considered very nearly if not quite within the range of demonstrated facts, but it is in determining the particular group of mammals from which the Cetacea arose that greater difficulties are met with.

One of the methods by which a land mammal may have been changed into an aquatic one is clearly shown in the stages which still survive among the Carnivora. The seals are obviously modifications of the land Carnivora, the Otaria, or Sea-Lions and Sea-Bears, being curiously intermediate. Many naturalists have been tempted to think that the whales represent a still further stage of the same kind of modification. So firmly has this idea taken root that in most popular works on zoology in which an attempt is made to trace the pedigree of existing mammals, the Cetacea are definitely placed as offshoots of the Pinnipedia, which in their turn are derived from the Carnivora. But there is to my mind a fatal objection to this view. The seal of course has much in common with the whale, inasmuch as it is a mammal adapted for an aquatic life, but it has been converted to its general fishlike form by the peculiar development of its hind-limbs into instruments of propulsion through the water; for though the thighs and legs are small, the feet are large and are the special organs of locomotion in the water, the tail being quite rudimentary. The two feet applied together form an organ very like the tail of a fish or whale, and functionlly representing it, but only functionally, for the time has I trust quite gone by when the Cetacea were defined as animals with the "hinder limbs united, forming a forked horizontal tail." In the whales, as we have seen, the hind-limbs are aborted and the tail developed into a powerful swimming organ. Now it is very difficult to suppose that, when the hind-limbs had once become so well adapted to a function so essential to the welfare of the animal as that of swimming, they could ever have become reduced and their action transferred to the tail;—the animal must have been in a too helpless condition to maintain its existence during the transference, if it took place, as we must suppose, gradually. It is far more reasonable to suppose that whales were derived from animals with large tails, which were used in swimming, eventually with such effect that the hind-limbs became no longer necessary, and so gradually disappeared. The powerful tail, with lateral cutaneous flanges, of an American species of Otter (*Pteronura sandbachii*) or the still more familiar tail of the beaver, may give some idea of this member in the primitive *Cetacea*. I think that this consideration disposes of the principal argument that the whales are related to the seals, as most of the other resemblances, such as those in the characters of their teeth, are evidently analogous resemblances related to similarity of habit.

As pointed out long ago by Hunter, there are numerous points in the structure of the visceral organs of the Cetacea far more resembling those of the Ungulata than the Carnivora. These are the complex stomach, simple liver, respiratory organs, and especially the reproductive organs and structures relating to the development of the young. Even the skull of Zeuglodon, which has been cited as presenting a great resemblance to that of a seal, has quite as much likeness to one of the primitive pig-like Ungulates, except in the purely-adaptive character of the form of the teeth.

Though there is, perhaps, generally more error than truth in popular ideas on natural history, I cannot help thinking that some insight has been shown in the common names attached to one of the most familiar of Cetaceans by those whose opportunities of knowing its nature have been greatest—"Sea-Hog," "Sea-Pig," or "Herring-Hog" of our fishermen, *Meerschwein* of the Germans, corrupted into the French "Marsouin," and also "Porc-poisson," shortened into "Porpoise."

A difficulty that might be suggested in the derivation of the Cetacea from the Ungulata, arising from the latter being at the present day mainly vegetable feeders, is not great, as the primitive Ungulates were probably omnivorous, as their least modified descendants, the pigs, are still; and the aquatic branch might easily have gradually become more and more piscivorous, as we know from the structure of their bones and teeth, the purely terrestrial members have become by degrees more exclusively graminivorous.

One other consideration may remove some of the difficulties that may arise in contemplating the transition of land mammals into whales. The Gangetic Dolphin (*Platanista*) and the somewhat related *Inia* of South

America, which retain several rather generalised mammalian characters, and are related to some of the earliest known European Miocene forms, are both to the present day exclusively fluviatile, being found in the rivers they inhabit almost up to their very sources, more than a thousand miles from the sea. May this not point to the freshwater origin of the whole group, and thus account for their otherwise inexplicable absence from the Cretaceous seas?

We may conclude by picturing to ourselves some primitive generalised, marsh-haunting animals with scanty covering of hair like the modern hippopotamus, but with broad, swimming tails and short limbs, omnivorous in their mode of feeding, probably combining water plants with mussels, worms, and freshwater crustaceans, gradually becoming more and more adapted to fill the void place ready for them on the aquatic side of the borderland on which they dwelt, and so by degrees being modified into dolphin-like creatures inhabiting lakes and rivers, and ultimately finding their way into the ocean. Here the disappearance of the huge Enaliosaurians, the *Ichthyosauri* and *Plesiosauri*, which formerly played the part the Cetacea do now, had left them ample scope. Favoured by various conditions of temperature and climate, wealth of food supply, almost complete immunity from deadly enemies, and illimitable expanses in which to roam, they have undergone the various modifications to which the Cetacean type has now arrived, and gradually attained that colossal magnitude which we have seen was not always an attribute of the animals of this group.

Please to recollect, however, that this is a mere speculation, which may or may not be confirmed by subsequent palæontological discovery. Such speculations are, I trust, not without their use and interest, especially when it is distinctly understood that they are offered only as speculations and not as demonstrated facts.

THE AMERICAN OBSERVATIONS OF THE ECLIPSE

NEWS of the American observations of the last eclipse has now arrived, and although details are yet wanting, enough information has been sent to show us that, as was to be expected, the American observers have left their mark upon the work. The telegram given below has been forwarded to me by the editors of *Science*, and is one transmitted by Prof. Holden to Prof. Young on the arrival of the former at San Francisco :—

"*San Francisco, Cal., June* 11

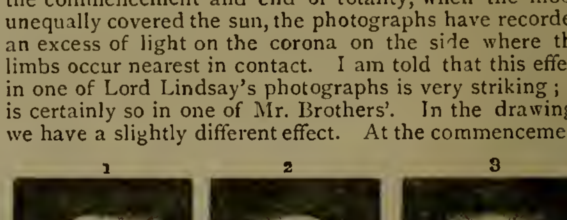
"American Eclipse Expedition arrived at St. Francisco June 11. Holden reports no Vulcan as bright as $5\frac{1}{2}$ magnitude. Hasting's observations prove the corona to be largely a phenomenon of diffraction by the great change in lengh of 1474 line on east and west sides of sun. No black lines in corona spectrum but D. Full observations with grating spectroscopes, prismatic telescope, and integrating spectroscope, by Rockwell, Upton, and Brown. Contacts by Preston. English and French parties successful. (Signed) E. S. HOLDEN"

It will be seen from the above that the spectroscopic attack was a very strong one, and although the telegram gives only the results of the work of Prof. Hastings, these are of unusual interest. I propose, therefore, to devote attention to them in the present notice. It will, however, be well to anticipate my remarks by a prefatory notice of the eclipse work on which it throws light. For this purpose I can scarcely do better than give the following extract from an article which appeared in the *Times* on Monday last :—

"It was only really in the eclipse of 1869 that we began to know anything about the corona, and it was only in the eclipse of 1870 that we began to appreciate what a very difficult problem was presented to us by that phenomenon. The then Astronomer-Royal and Prof. Maedler, to cite some among the eminent authorities writing after the eclipse of 1860, had come to the conclusion that the corona was mainly a non solar phenomenon. That *part* of it, however, was undoubtedly solar was admitted by all, for the reason that it was seen before and after totality. In the eclipse of 1870 the idea that part of it was really non-solar was enormously strengthened by a comparison of observations made by different astronomers. Its shape seemed to change as the moon swept over it, and this obviously, if it were true, implied some action of the moon's edge and reflection by something between the observer and the moon. In 1871, when the Government of India and the British Association took steps to have the corona photographed at the same time that it was carefully observed by the naked eye, the strange fact was first clearly indicated that the corona seen by the eye was a perfectly different thing to that recorded on the photographic plates. The explanation given at the time was that the coronal light was much more actinic than ordinary solar light of the same visible intensity, so that in the eye and on the photographic plate two different images were built up by different qualities of light proceeding from different sources. Hence the view was distinctly enunciated that the corona seen during eclipses was a dual phenomenon, partly solar, partly non-solar in its origin, the true solar corona being filamentous with variously-curved streamers, the visible corona being non-filamentous and consisting mainly of radial lines and rifts, extending to different distances from the edge of the moon"

This slight sketch may now be expanded by the following details. Thus, for instance, in March, 1870, Prof. Young, discussing the then current views of the corona, wrote :—"It is not impossible that the so-called corona may be complex, some portion of its radiance may perhaps originate in our own atmosphere, though I do not yet find myself able to agree with the conclusion of Dr. Gould and Mr. Lockyer in this respect, and I am strongly disposed to believe that the whole phenomenon is purely solar."

With reference to the eclipse of 1870 I wrote :—"At the commencement and end of totality, when the moon unequally covered the sun, the photographs have recorded an excess of light on the corona on the side where the limbs occur nearest in contact. I am told that this effect in one of Lord Lindsay's photographs is very striking; it is certainly so in one of Mr. Brothers'. In the drawings we have a slightly different effect. At the commencement



of totality, when the western or right-hand limbs were in contact, we get (see figure) 1 ; at the end of totality the appearance recorded was like 2 ; the picture at the middle of totality compounding both these appearances, and being roughly represented by 3, in which the rectangular appearance comes out in its full strength."

Let us pass on to the eclipse of 1871. This was my description, written at the time, of what I saw :—"There, rigid in the heavens, was what struck everybody as a decoration, one that Emperors might fight for; a thousand times more brilliant even than the star of India,—where we then were,—a picture of surpassing loveliness, and giving one the idea of serenity among all the activity that was going on below, shining with a sheen as of silver essence, built up of rays almost symmetrically arranged round a bright ring above and below, with a marked absence of

them right and left, *the rays being composed of sharp radial lines*, separated by furrows of markedly less brilliancy."

After there had been time to examine the photographic records of the eclipse in connection with the above description, the enormous difference between the photograph and the eye picture was fully recognised, and in my lecture at the Royal Institution on the eclipse, after referring to the actinic corona, to the striking similarity in the details of the photographs taken at different times and in different places, I said : "The solar nature of most, if not all, of the corona recorded on the plates is established by the fact that the plates, taken in different places, and both at the beginning and end of totality, closely resemble each other, and much of the exterior detailed structure is a continuation of that observed in the inner portion independently determined by the spectroscope to belong to the sun."

Passing from the photographs to the drawings, I pointed out that in Mr. Holiday's sketch, for instance, we got an infinite number of dark radial lines extending down to the moon, with a greater extension than in the photographs, though in some places the shape of the actinic corona and some of its details were shown.

Thinking that this difference might be explained by different lights being superposed, so that of two superposed lights the naked eye used one, and the photographic plate the other, I asked the question whether the facts might not be reconciled, and really harmonised with what was actually seen in the telescope, even by supposing that the visual image, this glare let us call it, was sifted in the telescope by using greater or less magnification in the same way as it was separated out on the photographic plates and in our eyes by the different qualities of the light producing the visual and photographic images.

From this point of view, therefore, I regard Mr. Hasting's observation as one of very great interest, and I believe that it throws light upon a good many prior observations. I do not think, however, that any one will go with him when he proposes to abolish a true corona at the sun, for the reason that the observations to which I have drawn attention show that it is really a dual phenomenon as I pointed out in 1870, and although diffraction at the moon's edge may be the cause of one part, it cannot be the cause of the other. It is, perhaps, almost too early yet to speculate upon the changes in our views of the chemical nature of the external boundary of the sun's atmosphere which may be brought about by a complete discussion of the question which these observations again bring to the front. I long ago pointed out that the fact of getting in the spectroscope an indication of a line at so many minutes of arc from the limb of the dark moon, was by no means a proof of the existence of a vapour or gas at that height above the sun. Maclear's observation in 1870 was of course the test, for the reason that if such a *caveat* were not available we must assume the existence of coronal matter between us and the dark moon. But in any case it is not too early to bear this in mind, that if in our spectroscopes we have been dealing with a true glare, from whatever cause produced, there will be an almost complete inversion necessitated, and in this way: the brilliancy of any particular wave-length of the glare may either depend upon the area of the surface at the sun producing light of that wave-length, or upon its inherent intensity. Now if we assume that only the inherent intensity is to be considered, then obviously the region of greatest temperature will cause the brightest light. The brightest light will therefore be produced in the lowest level of the solar atmosphere, but because of the glare it will appear to extend to the greatest distance from the sun. It may therefore have been that the line 1474, instead of indicating, as it has been supposed to do, that a substance which gives a line at the part of the solar atmosphere most removed from the photosphere is really produced by that part of the atmosphere, was produced at that part of the atmosphere nearest the photosphere, and really at first sight—although this is by no means a matter on which one would wish to commit one's self hastily—it does seem as if this view would harmonise a great many facts which are very difficult of explanation in any other way.

I discovered the line 1474 in the chromosphere on June 6, 1869, and up to that time no bright line had been observed beyond those belonging to the spectra of hydrogen, sodium, and magnesium, with the exception of one line of barium, which was first seen in March, 1869. Now we know from the long-extended series of such observations for which we have to thank the industry of the Italian observers, that the line 1474 is now seen more persistently than any line which is not recorded in the spectra of hydrogen, magnesium, and sodium. The eclipse of last year taught us, if it taught us anything, that the lines which are thus persistent are the lines produced at the temperature of the hottest layers, and, if subsequent inquiry strengthens the view that the height to which the line 1474 appears to extend is really due to the depth at which the substance which produces it is restricted, the persistence of 1474 in ordinary chromospheric observations will be at once explained.

J. NORMAN LOCKYER

AGRICULTURE IN JAPAN[1]

DR. LIEBSCHER'S little work is the result, the author tells us, of his investigations during an eight months' sojourn in Japan in 1880. A cursory glance at the contents shows that it bears the physiognomy of a strictly scientific work. The work is divided into five parts :—(1) The condition of the climate and its influence upon the land-products ; (2) the condition of soils and its influence upon the land-products ; (3) the social condition before the year 1868 (before the reformation) ; (4) the reformation and reorganisation of the State since the year 1868 ; (5) foreign commerce. I shall notice shortly each chapter with some remarks. Beginning with the first chapter, Dr. Liebscher commences with the monsoon, within whose sphere Japan is situated. It has, as is well known, a certain determined direction during the whole year. The summer (south-west) monsoon comes from the south-west from April to September, while the winter (north-east) monsoon comes from the north-east during the rest of the year. To the first, according to Dr. Liebscher, Japan owes its tropical flora, such as *Chamærops excelsa*, *Thea viridis*, *Cycas revoluta*, &c., and to the same he attributes the chief land-products, such as cotton, sugar-cane, tobacco, Indian corn, and rice. Why the summer monsoon is so favourable to the growth of the land-products is because, says the author, it causes a warm temperature, and the abundant precipitation of rain (maximum 1794 mm. in a year). He ignores then altogether the geographical position of Japan, that on one side she lies partly in a subtropical and temperate zone, on the other she is surrounded on all sides by a large body of water. The north-east monsoon brings a dry and terribly cold winter, though somewhat modified by the "Kuro-Siwo" current and this monsoon is the sole factor that renders the climate unfavourable, causing the remarkable phenomenon of the "freezing of the soil." Dr. Liebscher says, the regular course of the monsoon assures the people who happen to inhabit those lands which lie within the sphere of that wind, of a never-failing good crop of rice. Thus we are accustomed to depend solely upon rice, and

[1] "Japan's landwirthschaftliche und allgemeinwirthschaftliche Verhältnisse nach eigenen Beobachtungen dargestellt." Von Dr. G. Liebscher. (Jena 1882.)

consequently we become vegetarians. We cannot entirely agree with him, but rather lay more stress upon the influence of the Buddhist religion, which once wielded sway over us. As to the unfavourableness of the climate due to the monsoon, he is unfortunate in selecting as an example the Hakone region. The volcano of Fuji San (3784 m.) is a high peak covered with everlasting snow, and at the foot of this lies the Hakone Pass (804 m.). Here Dr. Liebscher had seen on the western side (toward Fuji) around the Lake Hakone, a dreary sterile slope; while the opposite mountains, lying on the south, are covered with a luxuriant growth of forest. He ascribes the cause of the sterility of the northern to the cold winter monsoon, and the thickly wooded ranges to the summer monsoon. I explain this striking contrast quite in another way. Fuji San is an active volcano, and at the foot of this lies the region referred to. It is natural that no tree will flourish at or near recent volcanoes, which send out an enormous quantity of scoriæ. Moreover the Hakone Pass is situated at a high altitude (804 m.). We find thick forest at the top of the Brocken in the Harz mountains. Could we expect the same at the summit of Vesuvius? The climate of Japan is not so ineffective as Dr. Leibscher has depicted in his work; in reality it is far more conducive to fertility than that of Germany.

The second chapter deals with the soil and its influence upon the agriculture. "A large tract of plain not far from Tokio is left uncultivated," says the author; "while the mountain slopes are turned into useful land. Such an irrational course is not difficult to understand when I consider the other deeds done by the Government and people." This is not so serious as it seems; he did not understand the irrigation of soils, which is of particular importance in the rice-producing countries. He mentions in another page that the total area of the empire is 38,243,640 hectares, of which the cultivated land occupies 4,508,482 hectares, *i.e.* 11·8 per cent.; while the area of Prussia is 34,823,420, with 17,435,605 hectares, *i.e.* 50·7 per cent. of the cultivated land. The balance is evidently against Japan. I must here remark that Prussia is not mountainous. The only notable range in the heart of Prussia is the Harz; the Thuringian forest, the Riesen and Sudeten mountains lie at the southernmost boundaries of that country; all the rest forms what is called the "North German Plain," levelled down uniformly by the Scandinavian glaciers in the Diluvial period. On the contrary, Japan is very mountainous. Moreover, it must be taken into account that we have newly taken possession of the Riū-Kiū Islands. The island Hokkaidô, Chi-Sima (the Kurile Islands) were neglected till thirteen years ago. They are now substantially incorporated into Japan, and the present Government is energetically striving to convert these into utility. From these circumstances the author is not justified in jumping to the conclusion as to the present state of things. We are glad to find that the yield per hectare in Japan is 35·62, while in Germany it is only 6·11 (Dr. E. Naumann). As to the geology, the bearing of which is of great importance to the soil and subsoil, Dr. Liebscher closely follows Rein's "Japan," without contributing his own observations. The chief rock-groups are: (1) the crystalline massive rocks (granite, diorite, diabase, porphyries); (2) the palæozoic schists; (3) the more recent volcanic rocks (trachyte, rhyolite, andesites, dolerite, basalt); (4) the alluvium and diluvium. Among the first group are phosphates, salts of potash and soda in the form of felspar, and apatite; and the same minerals are richly contained in the third group. In Rein's palæozoic schists, recent trias and cretaceous formations are ascertained by geologists of the Geological Survey, and must be separated from the second group of Rein's geological category. The author lays great stress upon the sterility of soils, to the extensive development of the talc and chlorite schists and so-called "tuff soils"—a fine volcanic ejectamenta poured from the vent, and sediment under water. Indeed, I saw, myself, in the provinces of Musasi, Sanuki, and Rü, the phyllite system, in which the talc and chlorite schists form an essential member; still they sink into insignificance when compared with the other rock groups. Moreover, the so-called talc schist is in reality micaceous clay slate, and the pseudochlorite schist is chloritic epidote hornblende schist. These facts will somewhat modify the author's conclusion. As to the "tuff soil," he discusses and repudiates the uncertain analyses of Prof. E. Kinch and Herr von Korschelt. Neither of these gentlemen, I think, are correct, supposing that their analyses have been carefully prosecuted. They select as samples the "tuff soils" from the neighbourhood of Tokio. This city lies in the plain, surrounded by lofty volcanic chains—Fuji, Asama, Sirane, and many other ranges of volcanic nature, bounded on the south-east by sandstone mountains of the Awa province. Tuff and sandstones, *a priori*, could not produce fertile soils, and indeed "tuff soils" are the poorest in Japan. It is not found everywhere in that country, and appears exclusively confined to the neighbourhood of Tokio. I doubt very much the nature of the so-called "tuff soil." It may perhaps be an accumulation of diluvial sand and gravels. If samples for chemical analyses were obtained, the soils from the Mino province among others, we should be able to get a true insight into the Japanese soils. The author's conclusions, based upon these unfortunately ill-chosen samples, could, of course, not be correct, because the premises are already wrong. It is remarkable that Dr. Liebscher, as a professional agriculturist, after travelling through the greater part of Japan, should not be able to throw some new light on this point.

On the third chapter I have little to say, for the description relates to the bygone world prior to the year 1868. At present, our social condition assumes quite a new phase. Moreover the facts are compiled from the *Transactions of the Asiatic Society of Japan* and from the *Mittheilungen der deutschen Gesellschaft für Natur und Völkerkunde Ostasiens*. Most of the *Transactions* are translations from old obscure Japanese documents under the guise of new titles. One thing cannot however be passed unnoticed, that is the footnote on p. 72, which runs as follows:—"The Mikado may have, according to the Land Statute, 12 wives; the nobles, 8; the samurai, 2; the commons, 1." No such law ever existed in Japan. We are neither Mormons nor Mohammedans!

The fourth chapter deals with the political and social changes since the year 1868. It presents nothing new, except some odd remarks of a fanciful nature. The full accounts are already worked out by Le Gendre in "Progressive Japan," in Griffis's "Mikado's Empire," and lastly in Rein's "Japan." On p 105 it is stated that the Japanese Government lays a heavy tax upon the farmer which may amount to half what he has won by patient labour; this oppressive measure would hinder future agricultural progress. In reality the legitimate tax is only 2½ per cent. of the net product.

The last (fifth) chapter treats of the historical development of foreign commerce and the balance of exports and imports. It is seen from the elaborately compiled tables that Japan is now in a favourable condition. In spite of the author depreciating and underrating what the Japanese have done, and the apparently incurably unfavourable physical conditions of the country, the author has, in the concluding chapter, a somewhat reassuring statement. He says that Japan will gradually produce more and more agricultural products if the heavy tax is taken off and serviceable roads are constructed throughout the interior. If this should be the case, the buying power of the country will be increased, and Germany will have to look for an opportunity to engross the export commerce. I must remark, lastly, that the author seems to me not fair-

minded in doing a great injustice to the Government of Japan, by which he was temporarily employed.

Munich B. Kotô

NOTES

At the annual general meeting of the Society of Arts, which was held on the 27th ult., Sir William Siemens being in the chair, the following resolution relative to the death of Mr. Spottiswoode, who was a vice-president of the Society, was passed:—"That this meeting of the Society of Arts desires to express the deep regret with which it has received the news of the death of Mr. William Spottiswoode, one of its vice-presidents, and its sense of the loss which the Society has sustained by his decease. In him England loses one of her most remarkable men of science, science itself one of its greatest ornaments, and all who knew him a sincere and valued friend. Besides devoting his own time and thought to the advancement of knowledge, he was ever ready to lend to all engaged in like pursuits the assistance of his experience and his wise counsel. In thus placing on record their own appreciation of his services, the Society desires to express its feelings of sympathy with his widow and his family, and also with the Fellows of the Royal Society, of which he was the honoured and beloved President."

The report of the Council for the past year, which was then read, makes it abundantly evident that the useful work of the Society is being carried on as successfully as heretofore. The *conversazione* of the Society previously fixed for the 11th inst. has been postponed to the 25th. On that day it will be held at the Fisheries Exhibition, South Kensington, when the Prince and Princess of Wales will be present.

Intelligence has been received from Vivi, on the Congo, of the sudden death of the well-known Swedish explorer, Capt. T. G. Een. Mr. Een, who was on his way to join Mr. Stanley on the Upper Congo, fell down dead from heart disease, just as the signal for his caravan to start was given.

The Vienna Academy of Sciences offers two prizes of 1000 florins each (about 84*l.*) for the best treatises (1) on the capacity of various crystals for conducting electrical currents; and (2) on the chemical constitution of albumen matter.

The well known Russian merchant Sibiriakoff is about to send another vessel to the Siberian rivers this summer. This is the steamer *Obe*, built of Bessemer steel at Motala in Sweden, and which will leave Gothenburg this week. The vessel, which is provisioned for sixteen months, is commanded by the Russian Capt. Weide, who has for many years sailed on the Yenisei and Lena. She will proceed to Tromsö, where she will meet his other steamer, the *Nordenskjöld.* A schooner with building materials will accompany the steamers as far as Novaya Zemlya, where it is intended to erect some storehouses at Yugor Scharr for the reception of cargoes when ice prevents the approach to Obi or Yenisei. At Novaya Zemlya a member of the expedition, Capt. Grönbeck, with two Samoyedes, will be left behind to study the ice and make meteorological observations during the winter. The *Obe* and *Nordenskjöld* will proceed to Port Dickson and the River Yenisei, in the mouth of which, in the Sastorovsky, the *Nordenskjöld* discharges her cargo, viz. merchandise, and loads a cargo of Siberian produce, with which she returns to Europe. The *Obe* proceeds up river with what cargo she can carry as far as Yeniseisk, and remains there for river navigation during next summer.

M. Thollon is now working in the Observatory at Paris. We are informed that the Pic du Midi Observatory is making great progress towards completion, and that Admiral Mouchez, M. Thollon, and other astronomers will visit it towards the end of August.

The monthly meeting of electricians has developed into a new institution, which is to be called Société des Électriciens. A committee has been established for determining the regulations to be proposed at a general meeting next October. M. Cochéry, Ministre des Postes et Telegraphes has been appointed honorary president of the society.

A remarkable instance of the fidelity and sagacity of the dog happened on Friday last at Milford Haven, and is recorded in the daily papers. Two men named Davies and Taylor were out in a boat which was swamped. The former of these was the owner of a dog, and whilst the men were struggling in the water the animal caught hold of Taylor with the object of supporting him; finding, however, that it was not his master to whom he was rendering this assistance, he relinquished his grasp and went to the aid of Davies, his master, supporting him until he was rescued by a passing steamer, the other man being drowned.

On June 13 at about 2 p.m. an earthquake was felt in the neighbourhood of Vossevangen in Norway. There was one continuous shock lasting several seconds, accompanied by a noise as that of a heavy train passing.

A new electric boat, exceeding in size all that have hitherto been designed, is now being fitted up at Millwall by the Electrical Power Storage Company, and is, we understand, nearly ready for her formal trial trip. The new craft is of iron, and measures forty-six feet in length. Her "engine" is a Siemens' dynamo of the D2 type, and works direct on the screw shaft without any gearing. The screw is of unusually narrow pitch, in order to enable the dynamo to run with a high velocity. She carries sixty-five accumulators of the Faure-Sellon-Volckmar pattern of the same size as those used in the smaller electric boat constructed last autumn by the same company. In the private trials made, a speed of eight miles per hour was maintained. This boat will be sent to Vienna, and will doubtless attract much notice at the forthcoming Electrical Exhibition in that city.

Rignold's panorama of the Arctic regions will be exhibited at the Royal Victoria Coffee Hall during the present month. This panorama, which was painted by the late Clarkson Stanfield, R.A., has the reputation of being the finest marine painting extant.

Under the title of "Hardy Perennials and Old-fashioned Flowers" Mr. L. Upcott Gill of 170, Strand, has issued the first number of what will be, if carried out on the lines here laid down, a rather bulky book, and moreover an expensive one, inasmuch as the number before us, which bears date April, is priced at 6*d.*, contains only forty-eight pages, and proceeds only to Cal. in an alphabetical arrangement of the names of the flowers which are recommended for cultivation. The aim of the work is a good one, namely, the bringing to notice many flowers for cultivation in our gardens that are now totally neglected or forgotten. Many old familiar friends are brought to mind in glancing through these forty-eight pages. The arrangement of the plants in alphabetical order of their scientific names is the best that could have been adopted. The wholesale use of capital letters for the specific names should be altered, and more care should be taken in the spelling, such mistakes occurring as *Achillea Ægyptica* for *ægyptiaca*, *Calthus* for *Caltha*, &c. Some of the figures also are extremely poor.

Since the above was written we have received the June number of this little work, which brings it down to *Helleborus* or the Christmas Rose. In this latest number the same lavish use of capitals occurs for the initial letter of the specific name

and the average number of mistakes also occurs. Thus under the genus *Funkia* the common name given is *Planting* Lily, whereas it should be *Plantain* Lily, a name that has been quite recently accorded to these plants by a gardening contemporary.

THE annual Reports of Colonial Botanical Gardens are so frequently reaching us and the matter contained in them is of such value and importance that we regret we have not space at our disposal to give a more extended notice of some of these records of scientific work in our widely spread dependencies. Two of these reports lie before us, namely, that of Dr. Trimen on the Royal Botanic Gardens, Peradeniya, Ceylon, for the year 1882, which report is dated at Peradeniya on January 1 of the present year, and that of Mr. Charles Ford on the Hong Kong Gardens, or rather on his work as Superintendent of the Botanic and Afforestation Department, Hong Kong. A large portion of Dr. Trimen's report is given to the consideration of economic plants, the first mentioned being coffee. Under this head it is with no satisfaction we learn that "Leaf disease has in no degree diminished, and the continued failure of crop during the past year has added to the difficulties of all concerned in the planting enterprise of the colony." Dr. Trimen continues, "No combined effort whatever to prevent the disease on the lines indicated by its known nature has been even attempted, whilst the waste of money and time in local applications of 'cures' has continued. As at the same time high cultivation and liberal manuring have become generally impossible from pecuniary necessities, the existing state of things, however much to be lamented, cannot be considered surprising. A remarkably wet season, too, has aggravated the condition of the badly nourished trees, and the low prices ruling for coffee have intensified the loss by short crops. Thus the cultivation of coffee has been in many places found not to cover expenses, and the necessity of growing other products has been more than ever forced upon proprietors." From this we gather that the prospects of coffee cultivation in Ceylon are anything but promising, and with regard to Liberian coffee, upon which the hopes of planters were at one time founded, we find that it likewise has had to bear the severe attacks of leaf disease, and consequently rises and falls in the estimation of planters. In suitable soils and localities, however, it does well, and the old trees now between eight and nine years old, though badly diseased, show no diminution in their crop-bearing capabilities. No record however is kept of the exports of Liberian coffee from Ceylon distinct from the produce of the other kind. Dr. Trimen remarks that the *Hemileia* not unfrequently attacks the fruits of Liberian coffee. As might be supposed, the subject of cinchona cultivation occupies a large portion of the report, and next to it comes tea and cocoa. The past year, we are told, has witnessed a very striking rise in the export of the first-named beverage, the exports amounting to 623,292 lbs., an advance on the previous year of 345,702 lbs. Tea estates have been opened at all elevations, and many old coffee estates not suited for cinchona culture are now cropped with tea. Indiarubber, guttapercha, and many other industrial and medicinal plants come under Dr. Trimen's review of a year's work at Ceylon, proving once more, if proof were needed, the value of the Peradeniya Gardens amongst others in promoting the advance of applied botany; and the same may be said of Mr. Ford's report of the Hong Kong Garden, for we find there that a considerable amount of attention has been given to the growth of such plants as *Cinnamomum cassia*, the tree furnishing Cassia Lignea of the London market, the Chinese varnish tree (*Aleurites cordata*), and the mahogany tree (*Swietenia mahogani*).

A NEW form of dry pile has been described in *Wiedemann's Annalen* by J. Elster and H. Geitel. In the previous forms of dry pile, from the time of Zamboni downwards, the disks of foil and paper have been placed in glass tubes, with the result that the film of moisture collecting on the inner surface of the tube has always exerted a more or less destructive influence. In the new dry piles the disks are strung with a sewing-needle upon a single strong silk thread, which insures better insulation. Messrs. Elster and Geitel have made the very interesting observation that piles of this type can be charged from a Holtz machine. An ordinary Zamboni pile of 11,000 pairs of disks of tin and copper foil gave, after ten minutes' charging, sparks one millimetre long, and was able to illuminate a small Geissler tube for some time with a discharge continuous at first and afterwards intermittent. Following up this analogy dry piles were constructed on the plan of a Planté battery. Thin disks of lead foil alternating with disks of silk paper painted with a mixture of soluble glass and peroxide of lead were strung upon silk strings. A charged pile of 7000 such plates gave for ten minutes a spark one millimetre long; and after twenty four hours still showed electrification.

THE last report of the British Consul at Tientsin supplies us with information respecting the only colliery at present in complete working order in China. This is at Kaiping, not far from Peking. The coal is said to belong to the true carboniferous system, and the bed dips to the south some forty-five degrees, forming a large basin under the Gulf of Pehchihli. No fear is entertained that the measures will run short. So far as has been ascertained, the coal bearing stratum is about one thousand feet, containing thirteen seams. During the winter months two hundred tons per day of the inferior kinds of coal can be sold to natives in the vicinity, who use it for pottery, brick, and lime-kilns; indeed, one of the most important results achieved by the opening of the colliery has been the revival of several industries in the vicinity which were languishing or extinct, on account of the surface coal of the district being mostly worked out, and the price of other coal being too high to be used with profit. In connection with the colliery is a small railway, the only one in all China. Its length is but six and a half miles, and at the terminus the coal is placed in barges and carried down by canal. After a little opposition the locomotives were allowed to run freely. But ironworks, which it was also intended to start, could not get over the superstitious opposition raised on the score of the proximity of the Imperial tombs, and the consequent geomantic disturbances caused by sinking shafts, &c. The iron ore is said to exist in enormous quantities, but it is not easy to work owing to the amount of silica present.

WE have received Parts 4–6 of the *Transactions of the Yorkshire Naturalists' Union*, which do credit to that energetic body of local naturalists. They are entirely occupied by lists and notes concerning the fauna and flora of this, our largest, county, so arranged that each subject has a separate pagination, and most of the authors give evidence of considerable bibliographical research; some of the articles are of far more than local importance.

FROM several parts of Sweden the appearance of an unknown caterpillar, which consumes the crops, is reported. Its length is from one inch to one and a half, and its colour grey-brown with green stripes. In one place it put in an appearance immediately after a violent storm with rain. The Academy of Agriculture has despatched an entomologist to visit the places from which it is reported.

THE German Society of Analytical Chemists offers two prizes, of 25*l*. and 15*l*. respectively, for the best treatises on cocoa and cocoa manufactures, with reference to their commercial value and efficacy in nutrition.

ADMIRAL MOUCHEZ will not be reappointed at the expiration of his term of office. The Government is fully convinced that it is useless to resort to this formality, and that it would be better to continue his appointment by *toute reconduction*, as is customary in France under peculiar circumstances.

MISS FIELDE, an American missionary lady stationed at Swatow, has, it is stated, completed a voluminous dictionary of the Swatow dialect, which will be published shortly.

THE additions to the Zoological Society's Gardens during the past week include a Feline Dourocouli (*Nyctipithecus vociferans* ♀) from Columbia, presented by Mr. H. H. Thiele; an Indian Civet (*Viverricula indica* ♀) from India, presented by Capt. Wilson; two Squirrel-like Phalangers (*Belideus sciureus*) from Australia, presented by A. Pretyman; a Vulpine Phalanger (*Phalangista vulpina*) from Australia, presented by Mr. J. E. Dothie; an Australian Crow (*Corvus australis*) from Australia, presented by Mrs. A. H. Jamrach; a Nicobar Pigeon (*Calænas nicobarica*) from the Philippine Islands, presented by Mr. Hugh Low; two Common Gulls (*Larus canus*), British, presented by Mr. C. W. Jervis Smith; a Spotted Mud Frog (*Pelodytes punctatus*) from the South of France, presented by Mr. H. P. Cambridge; a Cape Ant Bear (*Orycteropus capensis*), twelve Derbian Zonures (*Zonurus derbianus*) from South Africa, two Canadian Beavers (*Castor canadensis* ♂ ♀) from Canada, a Viperine Snake (*Tropidonotus viperinus*) from North Africa, a Tree Boa (*Corallus hortulanus*) from South America, purchased; a Hairy-footed Jerboa (*Dipus hirtepes*) from Arabia, a Simon's Dwarf Jerboa (*Dipodillus simoni*) from Algeria, received in exchange; a Japanese Deer (*Cervus sika* ♂), a Hybrid Syrian Wild Ass (between *Equus hemippus* ♂ and *Equus onager* ♀), an Impeyan Pheasant (*Lophophorus impeyanus*), four Amherst's Pheasants (*Thaumalea amherstiæ*), bred in the Gardens.

ON THE CAUSES OF GLACIER MOTION[1]

THE question of the causes which produce the movement of glaciers, which was at one time so eagerly discussed, would appear to have slumbered for the last ten years. This cannot be said to arise from the fact that a perfectly satisfactory theory has been developed, and recognised as such by all inquirers. The ambiguous allusion to the subject in Sir John Lubbock's presidential address to the British Association is an evidence that such certainty has not been attained. It is indeed generally supposed that the fact of the melting-point of ice being lowered by pressure is somehow at the root of the matter; but a full explanation of the origin of this pressure in the case of glaciers and of the mechanical features of the problem has yet to be given. I may therefore be pardoned if I draw attention to a different solution, proposed not by myself but by one of the greatest of English mechanicians. My apology for doing so is that I approach the question as an engineer, not as a physicist; and that it is in its essence, as will be shown immediately, a mechanical rather than a physical problem.

The following are leading facts of glacier-motion which must be accounted for by any valid theory on the subject:—

(1.) The phenomena of the movement of a glacier are simply those of a solid body in a state of flow.

(2.) The present glaciers of Switzerland and Norway, which are the only ones which have been critically examined, are mere shrunken fragments of the glaciers of the Great Ice Age. To take one instance, the present glacier of the Rhone is about 6 miles long and perhaps 500 feet deep; but the old glacier of the Rhone, which abutted against the Jura, was 120 miles long, and must have been 2000 to 3000 feet deep. The movement of such glaciers as this must also be accounted for in any satisfactory theory.

(3.) The glaciers of the present day are not confined to the temperate region; they are found in much larger numbers and of much greater size in the Arctic regions.

(4.) Both in the temperate and in the Arctic regions glaciers move in winter as well as in summer, and by night as well as by day.

That a glacier is in a state of flow was first proved by Forbes, and has since been confirmed by the measurements of Tyndall and others. Whilst the whole mass moves downwards, the top moves faster than the bottom and the sides than the middle; the upper layers must therefore be continually shearing over the lower, and the medial over the lateral. A glacier, being a body in a state of flow, must move under the influence of forces powerful enough to overcome its resistance, and so produce this condition.

The general phenomena of the motion of a glacier are exactly reproduced when a viscous body moves through a channel under the influence of its own weight. We have therefore first to inquire whether the shearing resistance of ice is sufficiently low to enable us to regard a glacier as a viscous mass.

The only experiments known to me on the shearing resistance of ice, are those of Moseley (*Phil. Mag.*, January, 1870). He found that, with pressures from 100 to 110 lbs per square inch, cylinders of ice sheared slowly across the two planes in contact, sliding over each other without losing continuity. The distance sheared through was about five-eighths of an inch in half an hour. A load of 119 lbs. per square inch was sufficient to shear through a cylinder of $1\frac{1}{2}$ inches in diameter in two to three minutes. From these experiments it would appear that the lowest shearing stress which will cause ice to flow is about 100 lbs. per square inch; but sufficient time was not allowed in the experiments to make this a matter of certainty.

There is another way in which the shearing resistance of ice may be tested. In the case of a block of ice of vertical sides, gravity of course produces a shearing resistance along all planes passing through the base. Let h be the height of such a block in feet, and consider the shearing force due to gravity on any square foot of a plane making an angle θ with the vertical. This shearing force is given by—

$$\frac{\dfrac{wh \times h \tan\theta}{2} \times \cos\theta}{h \sec\theta} = \frac{wh}{2} \sin\theta \cos\theta.$$

This expression is a maximum when $\theta = 45°$, and its value is then—

$$\frac{wh}{4}.$$

What is the greatest height at which a vertical cliff of ice will stand? I am not able to state this precisely, but it is very considerable. Mr. Whymper mentions crevasses in South America 300 feet deep. Cliffs of fully that height have been seen standing out of water in the case of icebergs, and as so small a part of an iceberg projects above water, these cliffs probably extend below to a considerable depth. Taking, however, only 300 feet for the value of h, or for the maximum height of an ice cliff, this would give about 30 lbs. per square inch as the lowest shearing force upon a plane of ice which would cause it to assume the condition of flow.

Let us now suppose a glacier of thickness a, lying upon a slope whose inclination to the horizontal is β; then the force per square foot, tending to shear the ice at its junction with the slope, is clearly $aw \sin\beta$.

Supposing $\sin\beta$ to equal $\frac{1}{4}$, and that the shearing resistance is 30 lbs. per square inch, we get $a =$ about 290. Hence we may say that a glacier lying on a slope of 1 in 4 will not move at all under its own weight unless it be at least 300 feet thick, and that, if it be more than this, the upper 300 feet will move as one solid mass, the part below alone representing the conditions of flow.

It is needless to say that there are hundreds of glaciers which are less than 300 feet thick, and which at no part of their course have a slope anything approaching 1 in 4.

We have now to show that the theories generally propounded for glacier action are all of them negatived by some of the foregoing considerations. These theories may be stated as follows:—

(1.) The glacier simply slides over its bed as a solid body. This is negatived by the fact that some parts move faster than others.

(2.) The glacier flows under the action of its own weight, exactly as a viscous body flows. This is the theory of Forbes. It is disproved by the facts given above, which show that even on a slope of 1 in 4 a glacier would not flow unless it was at least 300 feet thick.

(3.) The glacier moves by the crushing of its base. This has been disproved by Moseley's experiments, which showed that the crushing resistance of ice was considerably higher than the shearing resistance.

(4.) The glacier moves by the melting of its base. This is the theory of Hopkins. He placed a block of ice at 32° F. on a slab at a small angle, and found that it slowly descended as it melted. On this view the bottom of the glacier must always

[1] Paper by Walter R. Browne, M.Inst.C.E., read at the Royal Society, June 15, 1882.

be in a melting state. But glaciers are of all sizes and thicknesses, and they move in winter as well as summer. Bessels ("Die Amerikanische Nordpol Expedition," p. 398) measured the motion of an Arctic glacier (not apparently very thick), in the month of April, which is just when the winter cold would have sunk deepest, and found it considerable. Again in the *Zeitschrift des deutschen Geologischen Gesellschaft*, vol. xxxiii. p. 693, is an account of measurements of a Greenland glacier, both in winter and summer, which show that the motion in winter is only 20 per cent. less than in summer. It has been suggested to me that the interior heat of the earth may be sufficient to keep the bottom of the ice from freezing; but this cannot apply near the sides, where the ice is shallow, and the freezing of a very small strip on each side would be sufficient to keep the whole mass from descending. Moreover, this cause would apply to masses of snow as much as to ice. But it is known that masses of snow, though lying on steep slopes, do not descend in this way, even in summer, but melt away where they lie.

(5.) According to the theories of Tyndall, Croll, and others, the glacier moves not in the form of ice but of water. These theories are based on the known fact that the freezing point of ice is lowered by pressure. Hence it is supposed that certain parts of a glacier are continually being exposed to so much pressure that they melt. The water escapes downward, and the pressure being relieved it freezes again. The continuity of the glacier is further kept up by the process of regelation, according to which two pieces of ice, if placed in contact, form into one solid mass.

The advocates of this theory hardly seem to consider how very small the lowering of the freezing point is for any ordinary pressure. It is only ·0075° per atmosphere. In other words, it will require a pressure of 2000 lbs. per square inch to liquefy ice at 31° instead of 32°. This is equivalent to the weight of a column of ice about 5000 feet high. It is needless to ask whether such a pressure can exist within an ordinary glacier, while on the other hand glaciers undoubtedly move at temperatures far below freezing point—in the Arctic regions below zero.

It seems to be generally supposed that the pressure in the lower part of a glacier is due to the steeper upper portions: the glacier channel is spoken of as a mould, through which the ice is forced by pressure from behind. But in the upper glacier, slopes of ice or *nevé* are not uncommon at angles of 30° or even more. Such slopes usually do not even touch the more level parts of the glacier below them, but are separated from them by a wide, deep crevasse called a Bergschrund. Of this the well-known ice wall of the Strahleck is a conspicuous example. In other cases such slopes do not end in a glacier at all, but die away upon the mountain side. It is certain, therefore, that ice or *nevé* is able to maintain itself at a high angle upon its slope of rocks, and therefore cannot possibly exercise pressure upon the parts of the glacier far in advance of its foot. The fallacy of this idea may be further illustrated by referring, not to modern glaciers, but to those of the Great Ice Age. Can we suppose that the pressure of the snows about the sources of the Rhone was sufficient to drive that glacier down the valley to Martigny, round a sharp angle to the Lake of Geneva, through the bed of that lake, and on to the slopes of the Jura, a distance of more than 100 miles, in which the average slope was about 1 in 200; giving a propelling force per ton of ice of about 11 lbs. only?

All these theories have this in common, that they regard gravity as the sole and direct agent in the movement of glaciers, and the above considerations seem to prove that it is an agent far too weak for the work it has to do.[1]

The only other agent which has been suggested, or seems likely to be suggested, to account for the motion of glaciers, is heat. This suggestion, as is well known, is due to the late Canon Moseley, F.R.S., and was to some extent worked out by him in papers published in the *Phil. Mag.*, 1869 and 1870.

The mode of operation, on this theory, is well known. Ice is here considered merely as a solid body, obeying the ordinary laws of expansion and contraction under differences of temperature. This it is known to do, the coefficient of linear expansion, for 1° F., being ·00002856 (Moseley, *Phil. Mag.*, January, 1870), which is very high. When a mass of ice, such as a glacier, suffers a rise in temperature, either through conduction or radiation, it will expand; this expansion will take place mainly in the direction where movement is easiest, that is, down the valley. If from any cause the temperature falls, the glacier will again contract; but since the expansion is assisted by gravity whilst the contraction is opposed by it, the latter will be somewhat less in amount than the former, and when the ice has returned to its original temperature, its centre of gravity will have moved a certain small distance down the valley. By such alternate expansions and contractions the glacier moves gradually from the top to the bottom of its course.

That variations of temperature do take place in a glacier cannot be doubted, whatever be the condition in which it lies. This granted, the fact that it should move in the way described appears to me no more surprising than that the sheets of lead on which Canon Moseley made his well-known experiments did so move; and that the motion thus produced is of the character which answers to all the facts of the case, so far as they are at present known, can, I believe, be established.

The controversy occasioned by Canon Moseley's articles was unfortunately terminated by his illness and death, before the matter had been fully cleared up. The main objections urged to his theory were two. The first was that a glacier is not one continuous body (as assumed by Canon Moseley in his mathematical investigation), but is broken up into many parts by crevasses. But in the first place, the assumption above mentioned is merely one of convenience, and not in the least necessary to the theory. A detached piece of ice would move in the same way as a glacier, or as the sheet of lead did in Canon Moseley's experiments. Secondly, if a glacier is anywhere divided in its whole thickness by a crevasse, this is absolutely fatal to the gravitation theories, since there can be no pressure between the portions above and below this division. The only possible explanation of crevasses, on these theories, is that they are due to the glacier bending over a convex part of its bed. In that case the bottom half will be in compression, and only the top half in tension, so that the crevasse cannot possibly extend more than half way through the thickness.

The second objection was that the conductivity of ice is low; hence the effect of the heat would be confined to the layers near the surface, and could not account for the motion of the glacier as a whole. This objection does not seem to be confirmed by careful reflection upon the way in which such forces act. Let us suppose a glacier 100 feet deep, of which each successive foot expands and contracts alike throughout, but adheres with a definite shearing resistance to the layers above and below. Let there be a rise in temperature, which does not extend beyond the uppermost 10 feet. This layer will expand, and if it were free would expand to the full amount due to the increase in temperature. But its lower surface is not free. In expanding it will therefore drag the next layer after it, or in other words will cause it to expand also. The amount of expansion, however, will not be so great, because there will be a certain shearing extension at the plane of division between the two. The second layer will similarly cause an expansion in the third, and so on to the bottom. In consequence the energy which would all have been exerted on the top layer, had that been free, will be distributed over the whole of the layers; and the extension of the top layers will of course be much smaller than it otherwise would have been. Should the temperature then remain constant, the layers will retain their position, and adapt themselves to the new circumstances. If the temperature falls, the layers will contract, but from the now opposing effect of gravity they will not return to their original position. The top layer, which has extended furthest, will be the furthest below its original position; the second layer next and so on. If we suppose the layers to be indefinitely thin, we have the condition of things in an actual glacier. The ice in any vertical section will, on the whole, move down the slope, but the top will move faster than the middle, and the middle than the bottom, exactly as it is known to do. The same holds with regard to a horizontal section. At the sides the ice will be held back, not only by the friction, but also by the protuberances of the rock, which compel the ice to shear over them. Hence the velocity there will be retarded, and will be less than that in the middle, which is comparatively free.

A more important objection remains to be considered, which is this. On the present theory the motion at any point on the surface of a glacier will be not continuous, but oscillating alternately downwards and upwards, and the net distance by which it has descended, say, in a day, will be a mere fraction of the total distance through which it has moved in that period. If

[1] Another evidence against pressure from behind as a cause of motion is furnished by the very small size of many glaciers. Some of these, notably those of the class called "glaciers remaniés," are only a few hundred yards long, and cannot be many feet deep.

so, this alternate motion ought to have been noticed in the various observations which have been made upon glaciers, and this does not appear to have been the case. But, in reply to this, it may be remarked that most of the observations have only given the net movement of points on the glacier during intervals of a day or more, and therefore would not show the oscillations. Again, such observations have always been at points near the end of a glacier. Now the variations in temperature of a glacier will be very different at different parts, and the motion of the end of the glacier will, to a great extent, show the average result of these different advances and retreats in different parts of the higher regions. This average result will, of course, be a steady progression down the valley, and the oscillatory movement at the end of the glacier may be so much masked by this as not to be readily observable. Lastly, it may be suggested as possible that a certain amount of expansion by heat may have the effect of giving a *set* to ice, so that it does not return to its original length when brought back to the same temperature. If this be so, the oscillations would be much less marked, and at the end of the glacier would probably be indistinguishable.

I may now draw attention to some phenomena of glacier action, which are explained by the heat theory, but which do not seem explicable on the gravitation theory.

(1.) It is well known that glaciers, when they emerge from a narrow gorge into a comparatively wide valley, spread out into a fan shape. The Rhone glacier is a well-known instance. A still better one is a small glacier in Norway, mentioned by Prof. Sexa, which spreads out to five or six times its previous width. Now the effect of gravity, acting on a mass as a whole, is to carry it in one single direction, that of the steepest slope. The only way in which gravity can produce such a spreading out is by the parts of the glacier shearing over each other in the manner of a viscous solid. But the phenomena of ice cliffs, as mentioned above, show that ice does not spread from this cause, so that the fact seems impossible to explain by gravitation alone. On the heat theory it is, of course, perfectly easy: the expansion and contraction will take place in all directions where there is freedom to move.

(2.) Connected with this phenomenon is that of the longitudinal crevasses seen near the edges of glaciers, and particularly where they spread out in the manner just described. Now on the gravitation theory, as remarked above, the only possible explanation of a crevasse is that the ice is bending over a convex surface, and that its upper part is thus placed in a state of tension, under which it breaks. Since, on the gravitation theory, every part of a glacier is exposed to a severe pressure from behind, this explanation does not fit very well even for transverse crevasses; but to longitudinal crevasses it is clearly inapplicable, since the bottom of a valley is seldom or never convex in the direction of its width. On the heat theory the explanation is simple. We may suppose the heat energy communicated per square foot of surface to be about the same, whether near the middle or edge of a glacier. This energy is expended in producing an expansion throughout the whole thickness of the glacier, as described above. Hence the smaller this thickness, the greater will be the amount of expansion, and the greater therefore the net motion which results. Hence the thinner parts of a glacier will always be tending to tear themselves off from the thicker, and thus longitudinal crevasses will frequently be found.

(3.) The striæ which are so marked a feature of glacier-worn rocks become more easily explained on this theory. I have seen such striæ, even in the hard hypersthene of Skye, which were a considerable fraction of an inch in depth. When we consider the enormous force necessary to plough out such a furrow in hard rock, it is almost impossible to believe that it was done by the simple passage over it, once for all, of a stone imbedded in the ice. If, however, the stone descended by a series of oscillations, so that it passed many times over the same spot, this difficulty is greatly lessened.

(4.) In conclusion I may point out that the advocates of the gravitation theory are bound to explain what becomes of the heat energy which is poured into a glacier. When the sun is shining this radiant energy is always very large, although the temperature of the air may be low. In such cases the glacier does not melt; it is perfectly clear that it must expand, as any other solid must expand under the action of heat. If so, it seems unreasonable not to hold that the gradual descent by alternate expansion and contraction must follow, as it is known to follow in the case of other materials.

On the subject of the motion of Arctic ice, Dr. Rae, F.R.S., has kindly permitted the publication of the following particulars:—

"When in Greenland, in the autumn of 1866, I was ice-bound at the head of one of the fiords, and slept a couple of nights at an Eskimo's house. A glacier about half a mile distant was then in full activity, the movement of which might, I believe, have been as visible to the eye as it certainly was audible to the ear.

"My own idea is that Arctic glaciers must have a downward motion more or less during the whole year, summer and winter. I believe the alternation of heat and cold—or, I should rather say, of temperature—would of itself cause motion, especially near the upper surface.

"We know that ice 2 or 3 feet or more thick contracts very considerably in a few hours by a sudden fall of 15 or 20 degrees of temperature. I have found cracks in Lake Winnipeg 3 or 4 feet wide, formed by this cause during a single night, almost stopping our sledge journey. This gap soon freezes up. Then the weather gets milder, the ice expands, and with the new additional formation is too large for the lake, and is forced up into ridges. This process goes on at every 'cold snap,'[1] alternating with milder weather. Now supposing a glacier for 10 or more feet of its depth contracts by cold, as lake ice is known to do, it will get a series of cracks probably in its longest axis, say from inland seaward; the first snowdrift will fill up these cracks or some of them, and this filling up will to some extent perform the same office as the freezing of the cracks in the lakes. The longitudinal extent of the glacier will be increased. A snowstorm always brings milder weather, which would expand the glacier, but as this expansion would naturally tend downhill, instead of up, the whole motion would be downwards. But even if the cracks I mention did not take place, the contraction by cold would pull the ice downhill, not up, whilst the expansion by increase of temperature would tend to *push* the glacier downhill, so that these opposite actions would produce similar effects in moving the glacier, or such part of it as could be acted upon by external temperature, downwards.

"I may also add that when a crack, however slight, is formed by contraction, the cold is admitted into the body of the glacier, and increases the contracting power or influence."

SCIENTIFIC SERIALS

Annalen der Physik und Chimie, xix., part 4.—Electrical experiments: electric pressure on solids, by G. Quincke. This paper forms a continuation to a series of experiments in electrostatics published by the author in previous numbers of the *Annalen*, under the title of "Electric Expansion." It is illustrated with twenty-six cuts, and will be followed by a communication on the resistance of insulating fluids to electric force.—On electric disturbance at contact of gases with bodies in combustion, with four illustrations, by Julius Elste and Hans Geitel. The authors arrive at the general conclusion that all flames may be regarded as streams of hot gas, which generate negative electricity in burning electrodes introduced from without, as well as in small bodies in combustion suspended in them.—On electric vibration, and more especially on the phenomena of polarisation produced by vibratory movements, with four illustrations, by A. Overbeck.—On the dependence of gases as heat conductors on the state of the temperature, with three illustrations, by A. Winkelmann.—On the fundamental equations of E. Ketteler's theory of optics, by W. Voigt. The author shows that, so far from flowing from the principles of the doctrine of elasticity, Ketteler's fundamental equations are diametrically opposed to them.

THE *Journal de Physique* (May, 1883) contains the following original papers:—On the difference in barometrical pressure at two points in the same vertical line, by J. Jamin.—On the action of heat upon boracite and upon sulphate of potash, by E. Mallard.—On the penetration of actinic rays into the eye of man and that of vertebrates, and on their vision of ultra-violet rays, by E. de Chardonnet.—On a new apparatus for verifying the laws governing the fall of bodies, by M. Paquet.—On an experimental demonstration of the unequal velocity of the transmission of sound in gases and solids, by F. Griveaux.

[1] "Cold snap," an American term meaning a rather sudden increase of cold.

Zeitschrift für wissenschaftliche Zoologie, Bd. xxxviii. Heft 2 (April 27, 1883), contains:—Contribution to a knowledge of the infusoria, by Dr. G. Entz (Plate 8).—On the primordial skull of some mammalia, by Fred. Decker (Plate 9).—On some Cœlenterata of the South Sea, by Dr. R. v. Lendenfeld, of Melbourne, Part II.—On new Aplysinidiæ (Plates 10 to 13).—On the embryology of Hydra, by Dr. A. Korotneff (Plate 14).—On the larval development of *Phoxichilidium plumulariæ*, nov. sp., by Dr. R. v. Lendenfeld, with woodcuts.

Rendiconti of the *R. Istituto Lombardo di Scienze e Lettere*, May 10 and 17.—Preliminary inquiry into Zanardelli's proposed penal code (continued), by Prof. A. Buccellati.—On the commentaries of Gaius and the paraphrase of Theophilus, by Dr. C. Ferrini.—A few remarks on the first five sections of Ricardo's chapter on value, by Prof. E. Nazzani.—On the mortality of infants in the various provinces of Italy, by Prof. G. Sormani. The death-rate during the first month is shown to be much higher in winter than in summer, and in the northern than in the southern provinces. Thus: 50 per 1000 in Palermo, 190 in Padova, medium for the kingdom 91·9.—On the formation of the primitive line and primitive cleft in the gastrula of the Mexican axolotl, by Prof. G. Bellonci.—Alterations in the lower hollow vein aggravating hepatic cirrosis, by Prof. A. de Giovanni.—Observations on the comet of Brooks made in the Brera Observatory, Milan, by G. V. Schiaparelli.—On a deposit of fossiliferous Pliocene clay recently discovered near Taino, to the east of Angera, in Lombardy, by Prof. T. Taramelli.

SOCIETIES AND ACADEMIES

London

Linnean Society, June 21.—Prof. P. M. Duncan, F.R.S., vice-president, in the chair.—The following gentlemen were balloted for and elected Fellows of the Society, viz. Messrs. E. J. Baillie, J. Borland, K. McKean, E. C. Malan, and H. A. A. Nicholls.—A specimen of *Polyporus sulfureus* was exhibited for the Rev. A. A. Harland, obtained from the stem of a yew tree in the Cliveden Woods, Bucks.—A series of fossil fruits, &c., from Australia were shown for Dr. Charles E. Barnard; among these were species of *Phymatocaryon*, *Eisothecaryon*, *Ochthodocaryon*, *Spondylostrobus*, *Plesiocapparis*, and others.—Mr. W. T. Thiselton Dyer exhibited several interesting vegetable economic products, and made remarks thereon. Of a species of wax extracted by Mr. D. Morris of Jamaica from *Myrica microcarpa*, it was stated that while the berries are used for obtaining wax in South Africa, the West Indian fruits had not hitherto been used for this purpose. A gray, camphor-like substance, the product of *Artemisia noxa*, he mentioned as a rare example among the Compositæ; and there was a probability that this camphor was used in the production of Indian ink by the Chinese, and gave the peculiar aromatic odour to the true China ink. A rosary was shown made of fruits of *Trapa verbanensis*, De Not. (locally called Frutti de' Lago), from the Lago di Varese, Italy; also specimens of wax and candles made from *Rhus vernicifera* of Japan; the latter preparation is quite a local industry, which unfortunately is now ceasing on account of the rivalry of the cheap American oils.—The following plants were exhibited, viz., *Arnoseris pusilla* and *Hypochæris glabra*, obtained by Mr. Thomas Howse in West Surrey, and specimens of the Cheddar Pink (*Dianthus cæsius*), which had been grown freely by Mr. C. F. White on his garden wall at Ealing.—A paper on the structure of the hard parts of the Fungidæ (part 2, Lophoserinæ), was read by Prof. Duncan, and another by Mr. R. A. Rolfe of Kew, on the Selagineæ described by Linnæus, Bergius, and Thunberg.—A communication was read from Mr. H. G. Doran, on the malleus of *Rhytina stelleri*, based on a specimen obtained in the voyage of the *Vega*, and exhibited in the Swedish Department of the International Fisheries Exhibition, under the charge of Prof. Smitt of Stockholm. The author concludes that this auditory ossicle in the extinct Northern Sea Cow (*Rhytina*) is larger than in the Manatee (*Manatus*), and therefore it is the largest and bulkiest malleus to be found in the whole section of the animal kingdom where such a bone exists. In the character of its body it resembles that of the Manatee rather than that of the Dugong (*Halicore*); while in the manubrium it differs in *Rhytina* from the other Sirenia, and is far more generalised.—The following paper was taken as read, Notes on some new economic products recently received at the Royal Gardens, Kew, by W. T. Thiselton Dyer. Therein he treats of the West African indigo, the Inhambane copal, and the Ogea gum as exhibited at a previous meeting.—On the testis of *Limulus*, formed a communication from Mr. W. B. S. Benham. He describes the structures in question, noting the apparent isolation of many of the spermatic sacs, and the probability that they are not diverticula of the spermatic duct, but secondarily acquire connection therewith, the two structures being independently developed. He remarks that in no crustacean do the ducts of the generative glands form a network, whereas in the King Crab, as in the Scorpion and other Arachnids, they do.—There followed a paper on the Mollusca of H.M.S. *Challenger* (part xx.), by the Rev. R. Boog Watson. This contains a continued descriptive account of the family Bullidæ, dealing with the genera *Atys* and *Scaphander*, along with the group *Aplysiidæ*, genus *Dolabrifera*.

Zoological Society, June 5.—Osbert Salvin, F.R.S., vice-president, in the chair.—Mr. Sclater exhibited and made remarks on two birds obtained near Lima by Prof. W. Nation, C.M.Z.S., and on a collection of birds made in New Britain, New Ireland, and the Solomon Islands, that has been sent to him for examination by the Rev. George Brown, C.M.Z.S.—Mr. Sclater also called the attention of the meeting to a Condor from Peru, living in the Society's Gardens since 1877, which he was induced to believe was a specimen of the "*Condor pardo*," or *Sarcorhamphus æquatorialis*, Sharpe.—Mr. G. French Angas exhibited a collection of butterflies made during a recent visit to the island of Dominica, W.I.—A communication was read from Prof. Owen, C.B., entitled "Embryological Testimony to General Homology."—A communication was read from the Rev. O. P. Cambridge on some new genera and species of spiders. Eight spiders, representing as many new genera, were described: two of them belonged to the family Theraphoridæ, one to the Drassidæ, and the others to the Thomisidæ. Three of these species were from Ceylon, three from Caffraria, one from New Zealand, and one from California.—A communication was read from Mr. A. G. Butler containing an account of the Lepidoptera collected by Mr. H. O. Forbes in the islands of the Timor-Laut group. Examples of twenty-three species were obtained.—A communication was read from Mr. Herbert Druce containing descriptions of some new species of moths of the families Zygænidæ and Arctiidæ, mostly collected in Ecuador by Mr. C. Buckley. The number of new species described was fifty, belonging to twenty-four genera.—A paper was read by Messrs. Godman and Salvin, containing remarks on the variations of certain species of butterflies of the genus *Agrias*.—Mr. G. A. Boulenger read a report on a collection of reptiles and Batrachians from the Timor-Laut group of islands, formed by Mr. H. O. Forbes. Two new species were described—the one a lizard of the Australian genus *Lophognathus*, and the other a snake of the Indian genus *Simotes*, proposed to be named respectively *L. maculilabris* and *S. forbesii*. The snake was of special interest, as no species of the genus *Simotes* had hitherto been previously known to occur eastward of Java.

Chemical Society, June 21.—Dr. W. H. Perkin, president, in the chair.—The following gentlemen were elected Fellows:—G. S. Bowler, C. Beringer, T. H. Coleman, A. Esilman, H. E. Harrison, C. Hulke, H. Heap, B. Hobbs, C. T. Heycock, W. J. Livingston, B. P. Lascelles, H. R. Mill, M. F. Purcell, J. E. Richardson, F. G. Roberts, W. R. Reffel, A. Smith, E. H. B. Stephenson, A. W. Soward, A. H. Samuel, D. Wilson, and R. Williams.—The following papers were read:—On evaporation in vacuo, by H. McLeod. The author has contrived several forms of apparatus, and in the present paper describes two. One in which the water was evaporated in a glass dish with ground top, at a temperature not exceeding 50°, 50 c.c. evaporated in two hours; a Körtings water pump was used to obtain the vacuum. Instead of the dish a test tube or a combustion tube may be employed. In the second form of apparatus sulphuric acid was allowed to trickle down the tube into which the aqueous vapour passed, and thus the use of a condenser was avoided.—Note on a hydrocarbon and some substitution derivatives from camphor, by H. E. Armstrong.—On the preparation of the pentathionates, by G. S. Shaw. The author has reinvestigated this subject, because Prof. Spring states in *Liebig's Annalen* that he was unable to obtain pentathionates by using the method described by V. Lewes. The author completely confirms the results obtained by Lewes, and has obtained beautifully crystalline salts in which the ratio of potassium to sulphur was as 2 atoms to 5. A note is appended to the paper by Watson Smith.—On the decomposition of ammonium nitrate;

an investigation into the rate of chemical change, by V. H. Veley.—Note on the action of allylic iodide upon phenol in the presence of zinc or aluminium foil, by P. Frankland and T. Turner. Orthopropyl phenol was obtained.—On a new gas burner for heating combustion tubes, by W. Ramsay.—On a by-product of the manufacture of aurin, by A. Claparède and Watson Smith. When aurin is prepared from phenol, oxalic acid, and sulphuric acid, some quantity of white crystals appears on the lids of the aurin-pots. These were examined by the authors, and were found to consist of a phenyl ortho-oxalic ether.

Meteorological Society, June 20.—Mr. J. K. Laughton, M.A., F.R.A.S., president, in the chair.—The following papers were read:—On the structure of the ice-cloud disposed in threads, proposed to be called "cirro-filum," by the Rev. W. Clement Ley, M.A., F.M.S. Of the cirriform clouds one of the most important to the weather forecaster is that to which the author has given the name of "cirro-filum." Having from the time he was twelve years of age carefully studied this cloud whenever visible, and having for the last twenty-five years made it the subject of minute study, he is enabled to bring forward some results which may prove of value. The author then gives, first, a short account of the mode in which he was led to prosecute this study; secondly, a classification of the more recent and reliable observations; and lastly, an explanation of the principal phenomena observed.—Notes on a second series of experiments on the distribution of pressure upon flat surfaces perpendicularly exposed to the wind, by Richard H. Curtis, F.M.S. The results obtained in these experiments agree very closely with those of the former experiments.—On the reduction of wind records, by the Hon. Ralph Abercromby, F.M.S. The author discusses the significance and best method of deducing from anemographic records the total quantity, the quantity from different points of the compass, the relative frequency, the mean and annual velocity, the mean velocity from different quarters, the resultant, and the mean and diurnal direction of the wind.—The spectroscope as an aid to forecasting weather, by F. W. Cory, M.R.C.S., F.M.S.—Note on river temperatures as compared with air temperatures at Greenwich and Bremen, by Robert H. Scott, M.A., F.R.S. The author compares the results given in a recent paper by Sir G. B. Airy on a comparison between the records of the temperature of the Thames and those of air temperature taken at Greenwich with those published by Herr von Freeden for the temperature of the Weser as compared with that of the air at Elsfleth, close to Bremen, for the ten years 1858–67.

Physical Society, June 23.—Prof. Clifton in the chair.—New member, Mr. Stearn.—Prof. D. E. Hughes, F.R.S., exhibited a number of experiments illustrating his theory that a magnet is made up of magnetic molecules each of which is a small magnet. When a magnetic metal is in a neutral state he showed that there is a symmetrical arrangement of the molecules such as to make them satisfy their mutual attractions; not as on Ampère's theory a "higgledy-piggledy" arrangement. Prof. Guthrie stated that a piece of watch-spring magnetised retains its magnetism when impregnated with mercury. Prof. Everett, Mr. W. H. Coffin, and others remarked that Ampère's theory tried to account for the magnetism of the molecules. Professors Perry and Ayrton observed that when soft iron is between red and white hot, it ceases to be attracted by a magnet.—The new absolute sine galvanometer of Prof. Minchin was then exhibited to the meeting by Prof. G. Carey Foster. It is intended for the Cornell University, and measures less than the E.M.F. of a Daniell cell. The principle of the instrument was described at a former meeting of the Society. Prof. Ayrton, Lord Rayleigh, Mr. Coffin, and Prof. Clifton offered some remarks on the apparatus.—A note on the induction-balance effect and the densities of alloys of copper and antimony, by Mr. George Kamensky, A.R.S.M., was then explained by Prof. Chandler Roberts. These experiments were to determine whether the curve of the electrical resistance of the copper antimony alloys would be a straight horizontal line, U-shaped or of the L type. They were found to belong to the last type. It is seen from the curve exhibited that there is a rapid fall from copper to the alloy containing only 10 per cent. antimony, and this decrement is continued until the alloy $StCu_4$ is reached, when the curve turns rapidly and rises to $StCu_2$, then turns again, and passes to pure antimony. Prof. Roberts has shown that the alloy $SnCu_4$ occupies the lowest point of the curve, namely, the position that in the copper-antimony series is occupied by the alloy $StCu_4$. In the copper-tin series the second critical point is held by $SnCu_3$, and in the copper-antimony curve this point is held, not by Cu_3Sb, but Cu_2Sb, the formula for the violet alloy known to alchemists as the "regulus of Venus." The specific gravities were also plotted in curves, showing that the alloy Cu_2Sb does not stand out from the rest, while the alloy Cu_4Sb has a higher density than copper.

EDINBURGH

Royal Society, June 18.—Prof. Maclagan, vice-president, in the chair.—The Astronomer-Royal for Scotland presented a paper which was read by Prof. Crum Brown, on bright clouds in a dark night sky. This phenomenon Prof. Smyth had twice witnessed, on April 8, 1882, and April 30, 1883. On both these occasions the meteorological conditions were peculiar, the air being for a few hours remarkably dry. The explanation given was that the glow on the clouds was due to reflection of the gas-lights of Edinburgh from the hollow water-drops in the cloud, which from their floating in a very dry atmosphere had become sufficiently thin-walled to throw back a strong reflection from the two surfaces.—Prof. Tait read a mathematical note by Mr. Anglin, in which a solution was given of the problem to express x^m in terms of powers of x lower than n, when x^n is given in terms of these lower powers, and m is greater than n.—Prof. Tait communicated the results of his recent measurements of the compressibility of water. The water was compressed in a tube silvered inside and dipping with its lower and open end in a trough of mercury. The whole was placed inside the hydraulic press, and exposed to pressures of 1, 2, $2\frac{1}{2}$, and 3 tons weight per square inch, the compression of the water being measured by the height of ascent of the mercury, which was given at once by the lower limit of the silver film. For water, both fresh and salt, the compressibility was found to diminish with increase of pressure, diminishing at much the same rate in both cases, although to begin with the fresh water was more compressible than the sea-water in the ratio of about 72 : 67. The results obtained for the fresh water could be very accurately represented by the formula $c = \cdot 0072 (1 - \cdot 043 p)$, where c is the true compressibility per ton at pressure p tons weight per square inch. The mean temperature of the water was 12° C. At the same temperature alcohol of density ·83 showed a much greater compressibility (·01202 for one ton weight per square inch), which also diminished with increase of pressure—·01043 being the average compressibility for 3 tons weight.

SYDNEY

Linnean Society of New South Wales, April 25.—The following papers were read:—Notes on a collection of fishes from the Burdekin and Mary Rivers, Queensland, by William Macleay, F.L.S., &c. The new species described are *Serranus estuarius*, *Therapon fuliginosus* and *parviceps*, *Diagramma labiosum*, *Corvina argentea*, *Caranx compressus*, *Cybium semifasciatum*, *Platycephalus Mortoni*, *Eleotris planiceps*, *Atherinichthys maculatus*, *Mugil Ramsayi*, *Chatoëssus elongatus*, *Anguilla marginipinnis*, and *Taeniura Mortoni*.—By J. J. Fletcher, M.A., B.Sc., notes on a viviparous lizard. The author's attention had been drawn to the subject during last January, when he obtained at Burrawang several examples of female lizards in an advanced stage of pregnancy. The embryos were from two to three inches long, enveloped in a thin and transparent chorion quite devoid of the calcareous matter with which it is more or less impregnated in the oviparous species.—Notes on a method of obtaining water from *Eucalyptus* roots, as practised by the natives of the country between the Lachlan and Darling Rivers, by K. H. Bennett.—Prof. Stephens exhibited a photograph and a sketch forwarded by Mr. C. Jenkins, representing a fossil from the Devonian formation of the Murrumbidgee valley, near Yass. Mr. Jenkins is inclined to refer it to *Asterolepis* (which is closely connected with *Pterichthys*), but chiefly on account of the character of sculpture of the scales. On the same ground he doubts its relationship to *Cacosteus* or *Cephalaspis*. Prof. Stephens added that without the actual specimen before them with all its collected fragments, it would be premature to determine even the genus of this ancient fish, but pointed out that it appeared to have some points of resemblance to *Macropetalichthys* of the North American Devonians.—Mr. J. J. Fletcher exhibited a specimen of a giant earthworm, 25 inches long, from Burrawang, N.S.W. It probably belongs to Prof. M'Coy's genus *Megascolides*, and its existence in this colony is now recorded for the first time.

BERLIN

Physical Society, May 25.—Dr. Aron spoke on the glow-light coal, which, as is well known, is distinguished by its electrical conductibility and by its resistance to combustion when exposed to the atmosphere in an incandescent condition, and which thus resembles graphite, which possesses both these properties in a high degree. Experiments which were made in order to determine whether such good conducting and indestructible coal, as well as artificial graphite, could be made artificially, led to the result that organic substances, *e.g.* paper, cloth, wadding, when charred in vacuo at very high tempratures in graphite crucibles, acquire the property of resisting combustion and afterwards become good conductors. Wood-coal also, which, though it is with difficulty combustible, is a bad conductor, was converted into a good conductor by strong incandescence. When the incandescence and the subsequent cooling down were conducted in a stream of hydrogen, this had no effect upon the resistance to combustion. Soot, which was made incandescent under similar conditions, also acquired the properties of graphite in a high degree, so that for many purposes (*e.g.* in galvano-plastic work) soot that has been made strongly incandescent can be made to replace graphite. The property of leaving an impression which graphite possesses, and which makes it so well adapted to the manufacture of lead-pencils, was not acquired by the different kinds of carbon in the process of incandescence; very probably this property depends upon the crystalline composition of the graphite.

VIENNA

Imperial Academy of Sciences, March 8.—E. Mach, experiments and notes on the system of lightning-conductors of Mr. Melsens.—C. von Ettingshausen, contributions to the knowledge of the Tertiary flora of Java.—L. Pfaundler, on the mantle-ring machine of Kravogl, and its relation to the machine of Pacinotti-Gramme.—F. Hochstetter, sixth report of the Prehistoric Commission: on the mounds recently found at Watsch and St. Margarethen (Carniola).—F. Steindachner, on Japanese fishes.—G. Goldschmidt and R. Wegscheider, on the derivatives of pyrene.—R. Wegscheider, on some derivatives of opianic acid.—E. von Bruecke, on alcophyr, and on the true and the so-called biuret reaction.

April 5.—E. Mach, preliminary communication on new experiments made with the influence-machine.—F. Lukas, on the knowledge of the absolute strength of vegetable tissues.—W. Simerka, on the power of conviction (a mathematical study).—T. V. Tanovsky, on nitro and amido derivatives of azobenzene.—A. Nalepa, contributions to the anatomy of Stylommatophora.—A Lieben and L. Haitinger, preliminary communication on chelidonic acid.—E. Lippmann, on azylines.—B. Schwarz, on an eclipse of the sun mentioned by Archilochos. T. M. Pernter, psychrometrical studies.

PARIS

Academy of Sciences, June 25.—New methods of determining the right ascensions and absolute declinations of the stars (continued), by M. Lœwy.—Experimental studies in relation to the photometric observation of the eclipses of the satellites of Jupiter, by MM. A. Cornu and A. Obrecht.—A study of the deformations produced by sharp-edged tools in drilling, by M. Tresca.—On the employment of partial photographs in studying human and animal locomotion, by M. Marey. The object of this process is to avoid the great confusion caused by the superposition of numerous reflections in the case of slow locomotion. It is illustrated by a cut showing the attitude of the left leg of a man walking at a moderate pace and reflected at the rate of about sixty per second. The partial photographs obtained by this method enable the observer to analyse all kinds of motion, such as walking, running, leaping, and even action confined to one place.—On the action of mixtures of air with vapour of chloroform, and on a new process of anæsthesia, by Paul Bert. The experiments were made on dogs, which were treated with doses of chloroform diluted in varying proportions with air. From the effects observed it is hoped that many important problems may be solved connected with the action of this anæsthetic. But although all risk may thus be avoided in its application, the disadvantages inherent in chloroform itself cannot be overcome, and protoxide of azote still maintains its preeminence above all the anæsthetics.—On the reciprocal of homogeneity; similitude of mathematical formulas, by A. Ledieu.—Methods of separating gallium from ruthenium, osmium, arsenic, and selenium, by M. Lecoq de Boisbaudran.—On a case of long-standing hysteria, all the symptoms of which disappeared under the influence of aluminium, by M. Burcq.—On a method of computing secular perturbations in the elements of the orbits of planets, asteroids, comets, &c., by O. Callandreau.—A new generalisation of a formula of Lagrange, already generalised by Cauchy, by Em. Barbier.—On the relations of induction to electrodynamic action, and on a general law of induction, by M. Quet.—Automatic impression of telephotic despatches, that is, of despatches transmitted by light, memoir by M. Martin de Brettes.—On a method of determining by constant registration the slight movements of the crust of the earth. This method of recording microseismic movements was first suggested by MM. Bertelli and de Rossi, and forms the subject of a paper published in the *Engineer* for December 17, 1875.—On the sulphate of thorium, by Eug. Demarçay.—On a base derived from crotonic aldehyde, by Alph. Combes.—Researches on mesitylene, by MM. Robinet and Colson. A new glycol is described, and it is shown that the dichloride and the dibromide of mesitylene obtained by the action of chlorine and bromine on mesitylene gas are identical with the dichlorhydric and dibromhydric ethers of this gas.—Observations on the fermentation of breadstuffs, by M. Moussette.—On the concomitance of the anatomic and organographic characters of plants, by M. J. Vesque.—Borings at Rilhac, in the Brassac basin, east of Arvant, by M. Daubrée. These borings were most successful, revealing at a depth of eighty-six metres productive carboniferous strata underlying horizontal beds of clay and more or less argillaceous sandstones.—Borings at Toussieu, department of Isère, by M. Grand'Eury.—After piercing various alluvial, limestone, clay, and sandstone formations, coal was reached at a depth of 364 metres. These borings were begun after those of Chaponay had revealed carboniferous beds at the depth of 212 metres immediately below the marine molasse. The chief object of both is to determine the extension of the coal measures of the Loire basin under the tertiary plain in the north of Lower Dauphiny.—Scientific results of Col. Prejevalsky's journeys, and especially of his third expedition towards Tibet and the sources of the Yellow River, by M. Venukoff. Amongst the more important results were the animal and vegetable collections, comprising 408 specimens of 90 species of mammalia, 3425 of 400 species of birds, 976 of 50 species of reptiles, 423 of 53 species of fishes, 6000 of insects, and 12,000 of 1500 species of plants.

HYDRAULIC MANUAL

Hydraulic Manual. By L. D'A. Jackson. 4th Edition. Pp. xiv. + 307 Text + 184 Tables. (London : Crosby Lockwood and Co., 1883.)

THIS well-known text-book having reached its fourth edition, it is unnecessary to review it as a new work. The changes from the third edition are very great; the chief is the omission of the whole of the "Hydraulic and Meteorological Statistics" (about 224 pp. of tables); these relate chiefly to India, so that their omission is an advantage to the "Manual" as a general text-book, as it has enabled the text to be increased from 221 to 307 pp., and the general working tables from 104 to 184 pp., without increasing the bulk of the volume; the chief increase of the text is the introduction of an account of the great Roorkee hydraulic experiments.

Much stress is rightly laid on the small value of the old hydraulic knowledge; thus (p. 3) it is said, "Taken generally the mass of hydraulic science . . . prior to about 1856 may be considered superannuated. . . ." The most useful feature of this work is indeed its freedom from what is "superannuated," and its thorough adoption of recent experiment; the text is in fact in great part a short account of the great modern experiments. In detailing field operations the author has indeed preferred to give a "brief account of the modes adopted by various hydraulicians" as being "a far better guide to the engineer about to undertake the execution of gauging operations than any arbitrary advice or set of rules could possibly be." These concise accounts are on the whole well condensed; but the recapitulation—in some cases verbatim—of the several experimenters' own conclusions has the disadvantage that in several cases contradictory conclusions appear on different pages; this is inseparable from the progressive state of our knowledge of the motion of water when stated in this way; a little more discussion of the contradictory views would have been useful.

Kutter's general formula for mean velocity was early adopted by the author; its use as the formula to be preferred to all others for the case of canals (whenever velocity-observation has to be dispensed with) is now insisted on, much evidence in favour of it having been brought out by the recent large Roorkee experiments, with the very fair reservation however that Kutter's rugosity-coefficient (n) should at present be determined by actual experiment for each new channel, the data for its *a priori* determination (from the mere nature of the channel) not being as yet good enough. On the other hand it is rightly said that "to determine with accuracy the discharge of any ordinary or large river independent of velocity-observation is at present impossible."

A few minor details are worth notice. The units of measure, &c., adopted are an extremely simple and useful decimal system; they include the foot, the "foot-weight" of 1000 fluid ounces, *i.e.* the weight of a cubic foot of water at its greatest density, and a "league" of two London miles of 5000 feet each; this league is particularly suited to measurement of hydraulic slopes, a fall of 1, 2, &c., feet per league being at once seen to give a slope of 1, 2, &c., in 10,000. Two new very expressive names are introduced for two velocities, which recur very frequently in discussions on flow of water, viz. "verticalic velocity" and "transversalic velocity" for velocities past any vertical line or any (horizontal) transverse line in a channel section; these short terms will be a great relief from the wearisome periphrases hitherto in use, and merit general adoption.

A few suggestions towards improvement of the work may now be made. (1) In a purely professional work such expressions as "international recrimination," and "bureaucratic and heated with vanity" (p. 37) are surely out of place. (2) About one page of text and three of tables are devoted to the variation of gravity in different latitudes and at different heights; now the variation is so small that for the rough calculations of practical hydraulics this is an unnecessary refinement. (3) Among the "general notation" (p. 11) occurs the rather awkward phrase "g = velocity acquired by gravity in one second." (4) In finding the (trapezoidal) "section of maximum discharge" from the expression for discharge $Q = A\ V$ where $V = 100\,c\ \sqrt{R\,S}$ and $R = A \div P$, the argument used is that "under the condition of maximum discharge, A will be a maximum, so also will R; and when these are temporarily constant, P will be a minimum;" this argument might be considerably improved, somewhat as follows:—"Since $Q = 100\,c\,A\ \sqrt{R}\,.\,\sqrt{S}$, therefore Q is greatest (provided S be kept constant) when c, A, and R are all maxima together; now c is known (from experiment) to increase with R, and $R = A \div P$; hence Q will be greatest when A is a max. and P a min. at same time (provided of course that S is constant)": this argument is more general than that in the text; the effect of the S-variation is unknown. (5) About certain formulæ for "mean verticalic velocity," quoted from the Roorkee work, it is said (p. 209)—"The defect in these methods is evident; it consists in making the parabolic curvature dependent on one point or on two points, whereas three points are the least necessary." This last statement is a mistake; three points are necessary (for finding a mean ordinate) only if they be taken at random, but *two points are sufficient when suitably chosen*, as in the "two-velocity formulæ" quoted on pp. 87, 208 from the Roorkee work; these formulæ are in fact accurate for the parabolic form, and the proof of this (from the Roorkee work) is actually given at p. 87. The "one-velocity formulæ" are of course only approximate. It may be mentioned here that the writer has lately[1] discovered another (and far better) "two-velocity formula," also accurate for the parabola, viz. $U = \frac{1}{2}(v_{\cdot 211\,H} + v_{\cdot 789\,H})$, showing that the "mean verticalic velocity" is the arithmetic mean of the velocities at ·211 and ·789 (or say $\frac{2}{10}$ and $\frac{8}{10}$) of the depth: this new formula has several great practical advantages over any other yet published; among others, the two velocities can be measured at one operation with a single instrument (a compound "double-float" with two equal subfloats at the depths named), which is itself moreover susceptible of being made a more accurate instrument than any other of its class (double-float).

ALLAN CUNNINGHAM

[1] See *Proc. Inst. Civil Engineers*, vol. lxxi. pp. 18, 19, where the formula and instrument are both discussed.

ORIGINES CELTICÆ

Origines Celticæ (a Fragment), and other Contributions to the History of Britain. By Edwin Guest. Two Vols. (London: Macmillan and Co., 1883.)

A MAN'S foes are indeed those of his own household. More than one literary or scientific reputation has been injured by the injudicious zeal of a writer's friends to publish after his death the fragments and papers he has left behind. It is natural to imagine that the work and suggestions of a scholar must all be equally valuable, and that by omitting to print any portion of it the world may be a loser. But it must be remembered on the other side that a good deal which a scientific worker commits to manuscript is never intended to see the light, and that in any case it is unfair to him to publish fragmentary remains which he has never had the chance of revising and correcting.

Dr. Guest's name is deservedly one of power among all those who have interested themselves in the earlier history of our country. His papers on the Invasion of Britain by Julius Cæsar, on the Campaign of Aulus Plautius, on the Four Roman Ways, and on the Saxon Conquests in Britain, are all models of sound scholarship and careful method. Dr. Freeman acknowledges him as a master, and declares that "whenever they meet on the same ground, he ranks above Palgrave and Kemble." Friends and public alike, therefore, might have expected to find in the fragments of his unfinished work, "Origines Celticæ," a fresh monument to his historical sagacity and another contribution of importance to the ethnology of our islands.

But friends and public alike must be grievously disappointed by what is actually placed before them. It would have been far better to spare the paper and ink that has been expended upon it, and, what is of more consequence, the fair fame of the author himself. The "Origines Celticæ," which occupy the whole of the first volume and the opening pages of the second volume of Dr. Guest's posthumous works are a barren waste of unscientific theorising and uncritical collection of facts. The work carries us back to an age when the application of the scientific method to history was unknown, when ethnology and comparative philology were as yet undreamt of, and when the most amazing generalisations were built on the chance coincidence of proper names. In our search for the fathers of the Kelts we are transported to the Caucasus, to Egypt, and even to Ur of the Chaldees, and no shadow of doubt is allowed to cross the mind that Kimmerians and Kimbrians and Kymry are all one and the same people. The fact that there were Iberians in Georgia and Iberians in Spain is considered quite sufficient to prove that the early population of the Spanish Peninsula came from the sources of the Euphrates.

Dr. Guest's philology is as wild as his ethnology. He has heard of "Grimm's Laws"; but as their existence is inconvenient to his own etymological mode of procedure he denounces both the "laws" and their observers, though without understanding what they really mean. When Indo-European philology is treated in this way it is not surprising that the Rutennu of the Egyptian inscriptions are connected with the Assyrians of Resen, that initial *k* and *h* are said to interchange in Phœnician, or that an Egyptian settlement in Kolkhis is declared to admit of "no reasonable doubt."

Dr. Guest's turn of mind, in fact, was literary rather than scientific. Wherever the question was a purely literary one, he displayed erudition, patience, and common sense; where, on the contrary, it was ethnological or philological, he showed himself as helpless as a Jewish rabbi. The old well-threshed statements of Greek and Latin writers are heaped together, and tricked out here and there with references to the discoveries of Egyptian and Assyrian research. How little he knew of the latter, however, may be judged from the frequent mistakes he makes when appealing to them, as when, for instance, he insists on calling Sumer Sommari, or tells us that Assurbani-pal lived in the ninth century B.C.

Had the "Origines Celticæ" appeared a hundred years ago they would have been hailed as a profoundly learned and interesting book. There is no place for them in an age when the departments of knowledge with which they deal have been occupied by the method and spirit of inductive science. To know what Dr. Guest really was and of what he was really capable we must turn to the papers reprinted in the second volume of his remains, though even here we shall from time to time be reminded of the literary spirit which accepts what is not disproved rather than of the scientific spirit which doubts everything and holds fast only to that which is proved.

A. H. SAYCE

OUR BOOK SHELF

Handbook of Vertebrate Dissection. Part II. "How to Dissect a Bird." By H. Newell Martin, D.Sc., M.D., M.A., and William A. Moale, M.D. (New York: Macmillan and Co., 1883.)

SOME months ago we noticed in these columns (vol. xxvii. p. 335) the first of a series of Handbooks of Vertebrate Dissection, by Drs. Martin and Moale—"How to Dissect a Chelonian." The second, "How to Dissect a Bird," has now appeared, and, as the type selected is the pigeon, this volume will doubtless be appreciated by a large number of students.

The general arrangement of the book is much the same as that of its predecessor, directions being given how to proceed step by step, so that the student, with its aid, ought to be able to gain a good knowledge of the anatomical characters of a bird. The skeleton, in particular, is described in great detail, and there are four good figures and a diagram of the skull, as well as a figure of the hind limb. It is, however, to be regretted that there are no illustrations of the soft parts, for figures of the skeleton—at any rate of allied forms—can be got in almost any text-book on Comparative Anatomy, while satisfactory drawings of the viscera, &c., are not so easily obtainable.

The directions are on the whole excellent, with one or two slight exceptions. The description of the air-sacs, for instance, is very indefinite, and gives no idea of their true relations. If the authors had glanced through Prof. Huxley's recent paper on the subject in the *Proceedings of the Zoological Society*, and compared the air-sacs of the pigeon with the description there given, there is no doubt that the position of these structures and their relations to the lungs would have been stated more clearly.

We must also call attention to the following points, which are not very accurate:—

Only one pancreatic duct is described instead of three.

The inferior mesenteric artery, instead of the median sacral, is stated to be the termination of the aorta.

The descriptions of the thymus and thyroid glands appear to have been transposed.

The three divisions of the cloaca are not described, and the rudimentary right oviduct is not mentioned, though the "*Fallopian tubes*" are said to open into the cloaca.

It is a mistake to introduce questionable homologies into a book of this kind, especially when they are unsupported by fact. Thus the statement in § 118 that the "thin sheet of muscle which is closely adapted to the concave ventral surface of the lungs . . . represents the diaphragm of mammals," is certainly misleading. In the first place, the position and relations of these muscles are entirely different from those of the mammalian diaphragm, and, moreover, they receive their nerve-supply from the intercostals, the phrenic being absent. The fact that the phrenic arises so far forwards appears to indicate an entirely different origin for these two structures.

With these slight exceptions, however, the descriptions and directions leave little to be desired for clearness and accuracy. It is certain that accurate detailed directions are far more valuable for elementary teaching than more general ones; the student, once having mastered them, finds little difficulty in grasping the wider bearings of the subject. Such works as the present, therefore, which entail a careful examination of every point mentioned, not only save both student and demonstrator much trouble, but insure more accuracy in work. A series of pamphlets such as the authors intend to publish, treating of all the more important vertebrate types usually dissected in an ordinary course on comparative anatomy, will certainly prove most valuable.

An Easy Introduction to Chemistry. Edited by the Rev. Arthur Rigg, M.A., and Walter T. Goolden, M.A. New Edition Revised, pp. 148. (London: Rivingtons, 1883.)

THIS book is based on a "First Book of Chemistry," by Dr. Worthington Hooker, and is intended, we are told in the preface, "to convey information in respect to changes which are likely to attract the attention of young persons who observe and inquire."

It is questionable whether "young persons" do well in attempting to study chemistry; the chemical laboratory is not a place in every way suited to the requirements of youth, but without steady work in a laboratory no real progress in chemistry can be looked for. Should, however, any youth desire information regarding material changes which he observes around him, he will find a considerable amount of information in this little book; but should he be desirous to study chemistry, he will not we are afraid derive much assistance from this "Easy Introduction." Many experiments are described and numerous well-executed illustrations are given, but several of these experiments could not be performed by a beginner without the aid of a teacher or of much more detailed description than is given in the text. To read statements of the results of experiments is not the way by which young persons can acquire interest in or a knowledge of chemistry.

Although excellent in many ways, yet we cannot think this book will prove an efficient introduction to chemistry; a perusal of it may, however, serve to stimulate young persons to seek for an introduction to the science, some of the materials for the construction of which are put before them in this work.

Practical Electric Lighting. By A. Bromley Holmes, Assoc.Inst.C.E. Sixty-two Illustrations. (London: E. and F. N. Spon, 1883.)

IT is with pleasure that we shall watch the success of Mr. Holmes's little book on "Practical Electric Lighting." Mr. Holmes has clearly and simply put before the unelectrical public as much and no more of theoretical electricity as is necessary for his purpose, together with a good general summary of the chief machines and appliances in present use.

Besides this, much useful information is given in the last two chapters, first, on the present economic state of electric lighting, and second, on the best means of applying the power to electric machinery. If there be one point in the book not so strong as the rest it is that the descriptions of the dynamos and lamps would have been better if they had entered a little more into detail.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*

[*The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to insure the appearance even of communications containing interesting and novel facts.*]

Geology of the Congo

I HAVE received from one of the Baptist missionaries in the front of the Congo mission a basket of specimens of rocks and a letter giving some particulars of the geological structure of the localities. The letter may be interesting as the first news of this kind from the centre of Africa, on its western side, and I therefore place it at your service.

S. R. PATTISON

5, Lyndhurst Road, Hampstead, N.W., July 7

Liverpool Station, B.M.S., Stanley Pool, Congo River, S.W. Central Africa, March 15, 1883

S. R. PATTISON, Esq.

DEAR SIR,—Before leaving England in 1879 you made us a kind offer to render us any help in geological and mineralogical matters that lay in your power, and that kindness has been recalled to mind every time I have examined a piece of rock. I had seen such geological variety in the few parts of England that I had visited, that in my ignorance I was expecting to find a much greater variety out here and at least some fossil treasures. But in this, as you may guess, I have been disappointed.

In sending home some curios the other day, I inclosed a few native ingots of lead and copper, which I thought might interest you. They are "mined" in a district of the Bizunseke tribe called Noama, some twenty-five miles west-north-west of the Ntombo Mataka Falls of the river. I have not visited the place, but I believe de Brazza (concerning whom there have been some paragraphs in the newspapers lately) passed through this "mining district."

Although I believe that no metal from that part is ever sold to white traders, it is an important item in native trade with the far interior. Some are used to make bullets, others are recast to make anklets, &c. If the district is rich, or there is much silver in the lead, the French will perhaps work there.

The case of curios was sent away before I had intended. I had hoped to have added other things, and a piece of sandstone from the cataracts here.

Mr. Stanley indirectly hinted that Stanley Pool might be the crater of a volcano (extinct of course) which in old time had rent a rift in the hills, forming an exit to the pent-up waters of a vast interior sea. I am not sure how much of this was made public by him. It was, however, his opinion on our return from our first visit to the Pool. He speaks also of lava reefs, granite, gneiss, trap, &c.

Dr. Pechuël Lösche, late of the German Expedition, which spent some time (about five or six years ago) on the coast about the Kioilo and Chiloango Rivers, was for a short time in charge of the Belgian expedition here during Mr Stanley's absence. He assures me that there is no trace of igneous action above Isangila at least. There may be traces of such action at the Yelala Falls, which form the first bar to navigation from the sea. Between there and Isangila Falls quartz, slate, micaceous, and granitic (apparently) rocks are the rule.

Above Isangila limestone is abundant for about ten miles, above that slaty rocks are prevalent. Limestone crops out again about the country of the Basundi. This gives place to a red shale at the western boundary of the Babwende, and at the Ntombo Mataka Falls a red sandstone appears under the shale.

This sandstone is soft and is broken up and rounded into huge boulders, which are covered with a smooth, chocolate-coloured, ferruginous glaze, deposited by the river, and hardened by the sun. These boulders thus glazed might well have been regarded by Mr. Stanley as trap and lava, &c., while the large grain of the stone, together with the appearance of the blocks in some places might suggest its being granite. This sandstone with the exception of a little which is quartzitic, is the only rock I have seen between Manyanga and Stanley Pool, and is certainly the rock at the great Ntamo cataracts here.

On the hills and cliffs about the Pool there are some white shining patches, which I hear are sand, but I believe there is no calcareous rock in the neighbourhood. The pool itself is a strange break in the lines of sandstone hills, which, although now much eroded by water, are the remains, doubtless, of what was once a plateau, at the level of about 1500–1800 feet above the sea.

On the road to San Salvador from our old Musuka station we find boulders of ironstone and small nodules of the same, mixed with clay, on the top of quartz, micaceous, and granitic rocks. Limestone crops up in several places, but the principal formation visible is the ironstone clay. In all this country I have not met with a trace of a fossil of any kind.

When at Landana, about two miles south of the mouth of the Chiloango River, some months ago, I saw some stones from the cliffs which appeared to be almost identical with a Portland stone (?) which I have seen used in fortifications in the south of England. There were many fossils, but I could neither spare time to examine the cliffs nor carry many specimens, being on an express journey by hammock up the coast. This was the only occasion that I have met with any fossils in Africa, and that in a part of the coast now well known through the work of the German Expedition. The quartz, micaceous, slate, shale, and sandstone rocks of this part of the continent are a poor field for palæontologic research.

I am very curious as to the geological formation of the Congo Valley between this point and the Stanley Falls, but at present have learned nothing. I should expect, however, to find the sandstone the only visible rock.

I wish that I could speak with better acquaintance with the names of the rocks, but often I feel sorely puzzled. On our first journey to Stanley Pool we mistook some strangely shaped hills near to Manyanga for granite, but have since ascertained them to be singular relics of the sandstone.

I need not enter into details of our work, which are so fully and constantly reported in the *Missionary Herald*. Regretting that the information I can supply is so meagre,

Believe me, dear Sir, yours very truly,

W. HOLMAN BENTLEY

Intelligence in Animals

1. I OBSERVE that Dr. Romanes, in his very interesting work on "Animal Intelligence," has been good enough to notice an account given by me in NATURE, vol. xi. p. 29, of an instance of a scorpion committing suicide under special excitement. It may be well to remention the fact that in this case the rays of the sun, focused on the back of the scorpion by means of a common lens, were the exciting cause of the self-inflicted fatal sting; and to set the matter at rest it may be remarked that two witnesses who saw the experiment can corroborate my statements. On reconsidering the whole affair, however, it occurred to me that in wounding its own back the scorpion may have merely been trying to get rid of an imaginary enemy. The concentrated rays of the sun no doubt caused pain, and the sting was probably directed towards the seat of this in an automatic manner, as a defensive act. This seems to me a more feasible explanation than to regard the action as due to an instinct detrimental to the individual and to the species.

2. While writing on the subject of "animal intelligence," it has occurred to me that the following remarkable example is worthy of being put on record:—Some years ago, while living in Western Mysore I occupied a house surrounded by several acres of fine pasture land. The superior grass in this preserve was a great temptation to the village cattle, and whenever the gates were open, trespass was common. My servants did their best to drive off the intruders, but one day they came to me rather troubled, stating that a *Brahminy bull* which they had beaten had fallen down dead. It may be remarked that these bulls are sacred and privileged animals, being allowed to roam at large and eat whatever they may fancy in the open shops of the bazaar-men.

On hearing that the trespasser was dead, I immediately went to view the body, and there sure enough it was lying exactly as if life were extinct. Being rather vexed about the occurrence, in case of getting into trouble with the natives, I did not stay to make any minute examination, but at once returned to the house with the view of reporting the affair to the district authorities. I had only been gone a short time, when a man, with joy in his face, came running to tell me that the bull was on his legs again and quietly grazing! Suffice it to say that the brute had acquired the trick of feigning death, which practically rendered its expulsion impossible, when it found itself in a desirable situation which it did not wish to quit. The ruse was practised frequently, with the object of enjoying my excellent grass, and although for a time amusing, it at length became tiresome, and resolving to get rid of him the sooner, I one day, when he had fallen down, sent to the kitchen for a supply of hot cinders, which we placed on his rump. At first he did not seem to mind this much, but as the application waxed hot, he gradually raised his head, took a steady look at the site of the cinders, and finally getting on his legs, went off at a racing pace, and cleared the fence like a deer. This was the last occasion on which we were favoured with a visit from our friend.

Ootacamund, June 5

The Mealy Odorous Spot in Lepidoptera

THE mealy spot on the base of the front margin of diurnal Lepidoptera, which emits an odour supposed to serve for sexual purposes, is present only in the male. It is therefore most interesting to observe that this spot is not always present in different individuals of the same species. Among the numerous varieties of *Papilio priamus* proved by rearing to belong to that species, the spot in question is present only in *P. priamus*, and is wanting in the male of all the varieties which have come under my observation. *Callidryas eubule* has the spot present only in specimens from Florida; it is wanting in all specimens from other localities of the United States, including a large number from Texas. In *Colias electra* and *edusa*, Keferstein (*Wien. Zool. Bot. Gesell.* 1882, p. 451) states that after an examination of a series of males he has found the mealy spot only exceptionally present, and the same is supposed by him to be the case in other species of *Colias*.

It would be interesting to know how this exceptional presence of so prominent a characteristic is to be explained.

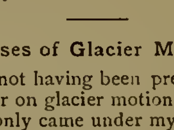
Cambridge, Mass., June 21

H. A. HAGEN

Causes of Glacier Motion

UNFORTUNATELY not having been present when Mr. W. R. Browne read his paper on glacier motion at the Royal Society on June 15, 1882, it only came under my notice when published in NATURE, vol. xxviii. p. 235. It is doubtless of little importance, but there is one sentence which does not seem to read exactly as I wrote it, namely, "It (a glacier) will get a series of cracks *in its longer axis*," should be "*across* (or transverse to) its longer axis," which I think makes the meaning more clear.

I may perhaps mention that when ice on lakes becomes from four to seven feet thick the effect of a sudden decrease of temperature does not, for obvious reasons, always cause a complete solution of continuity of the ice all the way through from its upper to its under surface, the crack being wedge-shaped, thus—



so that the water sometimes does not flow into the crack; the equable and higher temperature of the water counteracting at a certain point of the ice's thickness the penetration and consequent contracting influence of the colder air.

When the ice has acquired the great thickness above mentioned, the cracks by contraction are never so wide as when the ice is from one to three feet thick, but as far as I can remember they were more numerous, and when the water did not flow into them, were drifted full of snow by the first breeze of wind.

JOHN RAE

Sand

NOT having had the pleasure of perusing Mr. Waller's paper on sand, I gather from Mr. Gardner's notice of it that it is an attempt to distinguish by the aid of the microscope whether sand has been formed by the action of wind or of surf. Having a number of years ago become possessed with the idea that the form of the materials which make up the soils and subsoils found in any country might lead to a knowledge of the sources from which they had been derived, I had many soils and subsoils from Europe and Australasia looked at, but without being able to detect sufficient difference of shape or form as to lead to any definite result. Having been long familiar with the soils formed out of the boulder clay and drift of the south-east of Scotland, I had hoped to have seen a very marked difference in the form of the particles of sand existing in them from those of the interior of Victoria, New South Wales, and Queensland, large portions of the surface coverings of which countries are believed to have been deposited when covered with the sea. This difference exists certainly—that the soils of the boulder clays and drifts contain a far greater portion of fine and rough gravel, and rounder in shape than do those from Australia. Yet, so far as I could observe, the form of the sand was similar. It seems to me that both Messrs. Waller and Gardner are on the wrong track when searching solely for the typical forms of sand in the seashore or from torrents. The amount of sand found on the seashores of the world is large, no doubt, so is that from the rivers. What is that to the quantities contained in the surface coverings of the land? It is from this source the rivers obtain the supply they carry to sea or the shores, and make up the waste by friction. It has long seemed to me probable the sands, fine gravels, and silt formed by the passing of ice over the surface of the rocks would have a distinct form from the surface covering produced by other forces. The gravel or shingle of the rivers has a flatter shape than that of the seabeach when derived from the same rock. If such difference can be discovered in the silts, sands, and gravels derived from glacial action, it may be possible to assign limits to the extent to which ice has effected the present covering of the surface from the broken-up strata over which it has passed. Silt, sand, and shingle must all, however, be taken into account, and that from the deposits themselves, not from what has been subjected to littoral, fluviatile, or wind action.

Bonnington JAMES MELVIN

Garfish—Wild Fowl

WITH reference to Mr. Archer's note in NATURE last week (p. 226), may I remark that the beak of the garfish of southern waters (*Hemiramphus*, A.) is of rather too fragile a nature to be capable of making a slit of four inches in length in a hard felt hat? May not the fish in question have been more likely a young and small *Xiphias*—or, as is equally probable, a juvenile *Pristis* or sawfish—emulating with the thoughtless exuberance of youth the habits of *Exocætus?*

Any Australian can confirm the correctness of Dr. Rae's observations in the same page of NATURE *re* wild ducks and railways. Looking down upon the reedy waterholes on the south bank of the Yarra, from Princes Bridge in Melbourne, abundance of native waterfowl can any day be seen swimming about in conscious security and much less on the alert than they are in any swamp in the loneliest part of the bush. The constant roar of a great passing traffic, as well as the unceasing turmoil and unearthly noises of a large railway station within stone's throw of their haunts, is now quite unnoticed by these usually most watchful and wary of all birds.

But for the fear of trespassing on your space, I could give many more illustrations of the truth of Dr. Rae's remarks and of the quick and unerring instinct which so soon teaches both furred and feathered animals to dread less the roaring and shrieking ogre that is so swiftly tearing his way into their most secluded haunts in the uttermost parts of the earth than the silent, solitary biped who with gun in hand creeps stealthily upon them. ROBERT S. GOODSIR

Edinburgh, July 9

Glowworms

WHILE watching, last evening, some glowworms in a mossy stone wall, my attention was attracted to a firefly flying to and fro in the field beyond and approaching the wall where I stood. Arriving within two or three feet of the glowworm I was watching, he made several sharp zigzag flights, drawing nearer the light of the glowworm, and then, making a dash like that of a hawk at an object it has been watching, pitched directly on the glowworm, covering it in the fraction of a second. I had been noting the curious habit of this, which thus appeared to be the female insect, of standing with its abdomen erected in the air and quite motionless, except for a sort of pulsation, but on the contact of the male, the body fell to a normal position, and it was evident that coïtus was taking place. I watched them ten minutes until I was completely satisfied that this was the case, when I swept them both into a card box which I send with this for examination by a competent entomologist of the insects, which have not the slightest likeness to each other, the female resembling in general form the glowworm of England, but having an intenser light, and the light-emitting organs, beside the abdominal, which is the most luminous as well as the largest, being two glands (apparently) situated where the joints of wings might be expected if the insect were winged. The light is of an exquisite green, and so brilliant as to pale little at the proximity of a wax taper burning at six inches' distance.

This morning, on opening the box, I found the female apparently dead and collapsed; but the male, on the light returning to them, attempted to renew his embraces.

I remember a discussion at Cambridge (U.S.A.) some years ago, in which Agassiz conjectured that the light of the glowworm served as an amorous guide, but I had only a few weeks before noticed quite a different use for it. In one of the primitive forests of New York State, where twilight is normal from the density of the shade, I was attracted by the loud buzzing of a fly under a recumbent tree trunk. On looking for the cause of it I found a large, luminiferous insect resembling in general construction the common glowworm, but with powerful mandibles, which had built itself a little pit resembling that of an ant-lion, at the bottom of which it was lying, its light distinctly visible. The fly was in the clutch of the mandibles, helpless, though as large as a bluebottle, nor could I easily extricate him. There could be no more mistaking in his case that the light was a decoy than in this of the Pistoiese insect being a sexual invitation.

W. J. STILLMAN

Cutigliano, Pistoiese Apennines, June 25

[The name of the glowworm is *Lamprorhiza splendidula*, a common South European species.—ED.]

Mimicry

I HEARD what I fancy was rather a curious instance of mimicry last Wednesday evening (June 28) about 10 o'clock. I was walking with a friend across a field adjoining a meadow, in which was a landrail (*Rallus Crex*); we both noticed that the animal's cry, or crake as it is called here, was pitched in a higher and somewhat softer key than is usually the case, and my friend remarked that perhaps it was a young bird, but we were considerably surprised to hear him imitate the cry of the lapwing (*Tringa vanellus*). At first this cry was uttered only once alternately with several crakes, but we listened for about ten minutes, at which time, I suppose, he fancied that his note was perfected (which, however, it was not, being much less sharp than the pee-wit of the lapwing), and so he essayed it several times in succession. But he ultimately relapsed into his craking again.

Filston Hall, Shoreham, Kent, July 4 A. HALE

Indian Numeration

IN your review (p. 195) of "Field and Garden Crops of the North-Western Provinces and Oudh" you speak of the peculiar system of numeration used by the author, as in the instance 6,79,06,496, expressing sixty-seven millions, &c. Perhaps I may be allowed to point out that this marking is quite in accordance with the native Indian method of numeration, in which there is no word equivalent to "million." In India the series runs thus:—Thousands, tens of thousands, lakhs, tens of lakhs, krors (or crores). A lakh is a hundred thousand, a kror is ten millions.

It may be doubted whether it is advisable to adopt this system in an English book, for even native readers of it would easily enough follow our own; still it is not uncommon to see lakhs and krors made use of in English official papers.

Of three questions asked by the reviewer, the above remarks give an answer to one; as to the others I may say that a "seer" is two pounds avoirdupois, and a "maund" is forty seers.

Eton College, July 4 FREDERIC DREW

FUNERAL OF MR. SPOTTISWOODE

THE funeral of the late President of the Royal Society on Thursday last was impressive and solemn, and was a fitting end to the life that had passed away.

We take from the *Times* the following account of the general arrangements of the funeral :—

A large number of those who were present assembled in the Jerusalem Chamber, which the Dean had kindly placed at the disposal of the family. Those who by courtesy were styled pall-bearers met here—Dr. Evans, Vice-President and Treasurer of the Royal Society, the Marquis of Salisbury (Chancellor of the University of Oxford), Earl Granville (Chancellor of the University of London), Mr. Childers, Sir W. Siemens, the Duke of Northumberland, Sir Frederick Leighton, P.R.A., the Master of the Stationers' Company, Lord Aberdare, Sir John Lubbock, Mr. E. J. Stone, Sir Bartle Frere, Prof. Flower, Sir W. Armstrong, and, representing departments in the firms with which the name of Spottiswoode is connected, Mr. Shinn, Mr. Millwood, Mr. Carey, Mr. White, Mr. Howe, Mr. Wilson, Mr. Hamilton, and Mr. Straker. Others, who went first to the Jerusalem Chamber, were the Archbishop of York, the Bishop of Lincoln, Mr. Mundella, M.P., Mr. Shaw-Lefevre, M.P., the Dean of Christ Church, the Master of Balliol (Prof. Jowett), the Archdeacon of Maidstone, Sir Frederick Bramwell, Sir Richard Cross, M.P., Mr. Warren De La Rue, Sir Frederick Evans, Sir Joseph Fayrer, Sir James Caird, Lord Claud Hamilton, the Hon. George Brodrick (Warden of Merton), Mr. W. H. Smith, M.P., Mr. W. E. Forster, M.P., Sir Charles Dilke, General Sir H. Rawlinson, Sir James Paget, Mr. Irving, Prof. Huxley, Sir Joseph Hooker, Mr. Lecky, Sir Richard Temple, and Mr. J. Norman Lockyer. Some again, among whom were Lord O'Hagan, Sir Walter Stirling, Sir Henry Barkly, Sir James Cockle, the Dean of Wells, Mr. Philip Magnus, Director of the City and Guilds of London Institute, Mr. Trueman Wood, Secretary, and Mr. Wheatley, Assistant Secretary of the Society of Arts, Mr. Symons, F.R.S., of the Meteorological Society, and Sir John Kennaway, M.P., at once took their places in the choir or south transept, the seats in the north transept being reserved for *employés* of Messrs. Eyre and Spottiswoode and Messrs. Spottiswoode and Co.

Besides those who have already been named, the list of mourners invited to attend in the Jerusalem Chamber included the following gentlemen, of whom nearly all were present :—

Mr. Andrew Cockerell (representing his Royal Highness the Prince of Wales), the Lord Mayor, Mr. Gladstone, the American Minister, Count D'Aunay, Count Munster, the Lord Chancellor, the Earl of Northbrook, the Duke of Argyll, the Duke of Buccleuch, the Earl of Derby, the Earl of Ducie, the Earl of Dufferin, Earl Sydney, Sir Stafford Northcote, M.P., Lord Sherbrooke, Earl Spencer, Sir Frederick Abel, C.B., Capt. Abney, R.E., Prof. Acland, M.D., Prof. J. Adams, LL.D., Prof. W. Adams, M.A., Sir George Airy, K.C.B., Prof. Allman, M.D., Prof. C. Babington, M.A., Mr. John Ball, M.A., Mr. P. W. Barlow, F.G.S., the Earl of Rosse, Lord Chelmsford, Lord Eustace Cecil, Lord Lawrence, Lord Reay, the Marquis of Hartington, M.P., Lord Rayleigh, Lord Colin Campbell, Lord Carlingford, the Earl of Kimberley, Earl Amherst, Lord Houghton, the Bishop of London, the Dean of St. Paul's, the Bishop of Truro, the Dean of Salisbury, Mr. W. J. Farrar, Mr. W. H. Barlow, Mr. J. F. Bateman, F.G.S., Prof. Beale, M.D., Mr. I. L. Bell, F.C.S., Sir J. R. Bennett, M.D., Mr. George Bentham, F.L.S., Mr. Beresford-Hope, M.P., Sir Henry Bessemer, Mr. H. W. Blake, M.A., General Boileau, F.R.A.S., the Rev. T. G. Bonney, M.A., Mr. W. Bowman, LL.D., Mr. T. L. Brunton, M.D., Mr. G. B. Buckton, F.G.S., Sir C. J. Bunbury, Lord Cardwell, F.G.S., Dr. W. B. Carpenter, C.B., Mr. W. Carruthers, V.P.L.S., Prof. Cayley, V.P.R.A.S., Mr. Chamberlain, General Clark, R.A., Prof. R. B. Clifton, M.A., the Earl of Crawford and Balcarres, Prof. W. Crookes, F.C.S., Mr. T. B. Curling, F.R.C.S., Prof. G. H. Darwin, M.A., Prof. W. B. Dawkins, M.A., Prof. H. Debas, Ph.D., Prof. J. Dewar, M.A., Prof. Duncan, M.B., Mr. Edwin Dukin, F.R.A.S., Mr. W. T. Dyer, M.A., Sir W. Elliott, K.C.S.I., Mr. A. J. Ellis, B.A., Mr. Arthur Farre, M.D., Mr. Fawcett, M.P., Mr. James Fergusson, D.C.L., Prof. G. C. Foster, B.A., Dr. M. Foster, Prof. E. Frankland, D.C.L., Capt. Douglas Galton, C.B., Mr. Francis Galton, M.A., Dr. J. H. Gladstone, Mr. J. Glaisher, F.R.A.S., Mr. R. Godwin Austen, F.G.S., the Right Hon. J. G. Goschen, M.P., Lieut.-Col. J. Grant, C.B., the Right Hon. Sir W. H. Gregory, K.C.M.G., Sir W. Grove, Sir W. Gull, Mr. Albert Gunther, M.A., Prof. F. Guthrie, F.G.S., Mr. W. A. Guy, M.B., Sir W. V. Harcourt, M.P., Mr. A. G. Harcourt, V.P.C.S., Sir John Hawkshaw, Mr. Thomas Hawksley, M.I.C.E., Mr. R. B. Haywood, M.A., Mr. P. G. Hewett, F.R.C.S., Mr. James Heywood, F.G.S., Dr. T. A. Hirst, Prof. A. W. Hoffman, Ph.D., Mr. J. Hopkinson, M.A., Dr. W. Huggins, Mr. J. W. Hulke, F.R.C.S., Prof. Humphrey, M.D., Dr. J. H. Jackson, Dr. J. G. Jeffreys, Sir W. Jenner, K.C.B., Dr. J. C. Joule, Sir John and Lady Kennaway, Admiral Sir Astley Cooper Key, K.C.B., Prof. Ray Lankester, M.A., General Sir J. H. Lefroy, C.B., Mr. Joseph Lister, F.R.C.S., Admiral Sir F. L. M'Clintock, Sir H. Sumner Maine, LL.D., Prof. Marshall, V.P.R.C.S., Prof. N. S. Maskelyne, M.A., Mr. C. W. Merrifield, Mr. Alfred Newton, M.A., Prof. Odling, Mr. Daniel Oliver, F.L.S., Prof. Owen, C.B., Dr. John Percy, Mr. W. H. Perkin, C.S., Major-Gen. Pitt-Rivers, Sir Lyon Playfair, M.P., Dr. W. Pole, Mr. W. H. Preece, C.E., Prof. J. Prestwich, M.A., the Rev. Bartholomew Price, the Rev. Charles Pritchard, M.A., Dr. Quain, Sir A. C. Ramsay, LL.D., Prof. Osborne Reynolds, Admiral Sir G. H. Richards, C.B., Mr. G. J. Romanes, M.A., Prof. H. Roscoe, B.A., Mr. Osbert Salvin, M.A., Prof. Sanderson, Mr. P. L. Sclater, M.A., Mr. R. H. Scott, M.A., Mr. John Simon, C.B., Mr. W. W. Smyth, M.A., General W. J. Smythe, Mr. H. C. Sorby, LL.D., Mr. H. T. Stainton, F.L.S., Prof. Balfour Stewart, M.A., Prof. G. G. Stokes, M.A., General R. Strachey, R.E., Prof. J. J. Sylvester, M.A., Dr. Allen Thomson, Sir W. Thomson, LL.D., Mr. J. Todhunter, M.A., Prof. Tyndall, Dr. A. W. Williamson, Mr. W. H. Pollock, Mr. E. Bunbury, the Rev. B. Compton, Mr. Horace Davey, Q.C., M.P., the Head Master of Rugby, the Provost of Eton, the Head Master of Eton, the Hon. Ralph Dutton, the Hon. Robert Butler, Mr. Osborne Morgan, M.P., the Bishop of Exeter, Sir Louis Pelly, Sir Henry Thompson, Sir James Lacaita, Mr. J. Boehm, Mr. A. Milman, Mr. W. Hasseltine, Mr. F. Pollock, Mr. Pascoe Grenfell, Mr. T. Woolner, Mr. Lawrence T. Cave, Mr. T. H. Gordon, the Rev. W. H. Milman, Mr. T. Chenery, Mr. W. F. Burton, Mr. Douglas Freshfield, General Hutt, Dr. W. Grey, Dr. Priestly, Prof. Bryce, M.P., Mr. W. C. Cartwright, Sir Julian Goldsmid, Sir Louis Malet, Sir Rutherford Alcock, Sir Arthur Hobhouse, Sir Charles Mills, M.P., General Sir M. M'Murdo, General Sir Patrick Grant, Sir Charles Trevelyan, Sir James Stephen, Sir Charles Bowen, Lord G. Hamilton, M.P., the Recorder of London, Alderman Sir S. H. Waterlow, M.P., the Wardens of the Stationers' Company, Col. Donnelly, Prof. Ruskin, Cardinal Manning, a deputation from the Chemical Society, Mr. J. G. Dodson, M.P., Dr. Cumberbatch, Dr. Gibbons, Mr. Robert Browning, Mr. E. Chinnery, Mr. J. A. Froude, Sir R. Lingen, Mr. Herbert Spencer, the Dean of Llandaff, Sir Harry Verney, M.P., Lord Wolseley, Mr. Cyril Graham, Mr. Charles Eastlake, Mr. George Frere, F.R.S., Mr. Talfourd Ely, Sir Thomas Pears, Prof. Leone Levi, Prof. Max Müller, Mr. Frederick Verney, Mr. H. C. Hughes, and Major Gordon.

The body was borne from the house in Grosvenor Place to the Abbey on an open funeral car drawn by four horses. In the carriages immediately following the funeral car were Mrs. Spottiswoode, Mr. Hugh Spottiswoode, Mr. G. A. Spottiswoode, Mr. Cyril Spottiswoode, Mr. Rate, Mrs. George Spottiswoode, Miss Spottiswoode, Miss Augusta Spottiswoode, Mr. Arthur Brandreth, Mrs. Brandreth (sister of Mr. Spottiswoode), Mr. and Mrs. G. Noble Taylor, Mr. T. P. Beckwith, Miss Ellen Arbuthnot, Miss Mabel Spottiswoode, Mr. Adrian Spottiswoode, Mr. Norton Longman, Miss Longman, Miss Elizabeth Spottiswoode, Mr. Eyre, Mr. and Mrs. R. M. Bray, Mr. Frederick Arbuthnot, Miss Margaret and Master John Arbuthnot, Mrs. Beckwith, Mr. Sydney Beckwith, Mrs.

Jervoise, and Mr. Rate, jun. The servants came next in two carriages, and after the empty family carriage, the carriage of his Royal Highness the Prince of Wales, and then those of friends of the family.

At the entrance to the cloisters a company of the 2nd London Rifle Volunteer Regiment, formed of *employés* of the Spottiswoode establishments, stood with arms reversed as the procession passed through to the Abbey. At the West Cloister door, choristers, scholars, and clergy, the Rev. Flood Jones, precentor, the Rev. John Troutbeck, Minor Canon, Canon Rowsell, Canon Barry, Archdeacon Farrar, and the Dean, met the body. Immediately behind the chief mourners, and in front of those from the Jerusalem Chamber came, by special invitation of the family, Earl Stanhope, the Earl of Dalhousie, Sir F. W. Pollock, and Mr. J. F. Moulton; then Mr. Andrew Cockerell, representing the Prince of Wales, and among those from the Jerusalem Chamber, Mr. George Busk, Vice-President of the Royal Institution. The coffin, still covered with its lovely floral tributes, was placed under the lantern, while the 90th Psalm was sung to Purcell's Burial Chant, and the lesson was read by Canon Duckworth. As the notes of the anthem died away the body was borne to its last resting-place, near the grave of Archbishop Spottiswood. So great was the congregation of mourners, that not half the number could find standing room in the narrow aisle in which the grave is made. The Dean said the "Committal" and the prayers, and after the singing of Bishop Wordsworth's well-known hymn, "Hark, the sound of holy voices, chanting at the crystal sea," the Dean pronounced the blessing, and the mourners, casting into the grave the wreaths and bunches of flowers which many of them had carried, slowly dispersed. Dr. Bridge played the "Dead March" in "Saul" at the conclusion of the funeral service. The inscription on the plate of the coffin, which for sole decoration bore a Latin cross of brass, was—

WILLIAM SPOTTISWOODE,
Born January 11, 1825,
Died June 27, 1883.

A sermon *in memoriam* was preached in the Abbey by the Dean on Sunday afternoon.

THE ECLIPSE PARTY

LETTERS have been received from the English and American members of the above, giving some details which we think may prove of interest to our readers.

Leaving England on February 17 in the s.s. *Medway* the English observers made a calm passage to Colon. Here they met the American party, consisting of Prof. Holden, Dr. Hastings, Mr. Rockwell, Mr. Preston, Lieut Brown, and Mr. Upton, to which it will be remembered they were to be attached. The united party then proceeded to Panama, and took ship in the *Bolivia* for Callao, where they arrived on March 20. Early the following morning the instruments and baggage were removed to the U.S.S. *Hartford*, in which the voyage from thence was to be made, and the party left Callao about five o'clock on the evening of March 22, sighting Caroline Island, the spot selected for the observations, on April 20. Although named Caroline Island it is not a single island, but a low-lying chain of coral islets which enclose a central lagoon. The ring of islets is about seven and a half miles in length, and one and a half in breadth The island like most of its kind is of value on account of its stores of guano, and its cocoanut produce, being leased to Messrs. Houlder Brothers of 146, Leadenhall Street, whose agent at intervals visits this, and other Pacific coral islands leased to the firm. On the arrival of the *Hartford* a boat under the charge of Lieut. Qualtrough put off to make a tour of inspection, returning with the intelligence that there were two large empty frame houses, several smaller ones, and seven inhabitants—four men, one woman, and two children—who had come thither from Tahiti two months previously. A site having been selected by Prof. Holden for the erection of the observatory, the work of disembarkation commenced. This was a matter of great difficulty, the nature of the coast preventing even the small ship's boats approaching within several hundred yards of the shore. The boats had first to run in through a narrow opening in the reef, the boxes had then to be carried through fifty yards or so of water, varying in depth from two to three feet, next over about fifty yards of sharp irregular coral rock that cut the men's shoes to pieces, and finally to be carried up a soft sandy beach for upwards of a quarter of a mile. However, the landing was effected without accident, and the observers took possession of their various quarters.

The English observers report that the house in which they were located was a very comfortable one, containing a kitchen, dining-room, bed-room, bath-room, and store-room, and a large laboratory. Mr. Rockwell, one of the American observers, was fortunate enough to obtain the luxury of a bed. Mr. Upton, another of the party, had to be content with a table, whilst the rest swung their hammocks and cots in the verandah, an arrangement which, while possessing perhaps advantages of its own when the weather was fine, was not altogether the best when the nights were wet. Still the observers were not uncomfortable; and if they did not "fare sumptuously every day," yet, with abundance of fish and cocoanuts, they did not live altogether badly.

The weather, with the exception of one severe rain-storm, was pleasant during the sojourn of the observers, although nearly every day slight showers were brought to the island by flying clouds.

On the evening of the 22nd, just as the *Hartford* was casting off for Tahiti, *L'Éclaireur* came in with the French expedition, consisting of MM. Janssen, Trouvelot, Palisa, and Tacchini on board.

The preparations for the eclipse proceeded briskly, and by April 28 the siderostat, equatorial, and photoheliograph were erected and adjusted in position. The spectroscopes were next taken in hand, and the rating of the clocks proceeded with. This took some time; but matters had so far advanced by May 1 that from that date, with the exception of May 4, when the weather was wet, two rehearsals of the observations were made daily, one at 7, the other at 11.30 a.m. Messrs. Preston and Brown of the U.S. Coast and Geodetic Survey during this period made pendulum observations.

By the evening of May 3 the photographers were nearly ready to take trial plates, and these they hoped to obtain the following day. The hitherto fine weather, however changed, and before noon the next day five inches of rain had fallen, and the photographic dark room which had been erected was destroyed, all the dye being washed out of the ruby curtains and window. This damage being repaired, an attempt was made to obtain trial plates the next day, but the length of time occupied in rehearsing the observations, and the still unsettled state of the weather, prevented this being done. The early morning of the eclipse found the weather in the same unsettled state; about nine o'clock, however, the clouds began to disperse themselves, and by ten o'clock the sky was moderately clear. After the first contact the lenses were dusted, the slits of the spectroscopes cleaned, and the adjustments finally inspected.

With regard to the work of observation itself, this was done in accordance with the programme laid down before the observers left England, although the time-table of exposures was slightly departed from to meet the circumstances of the case, as, for instance, a greater length of totality than was expected, the duration being five minutes twenty-five seconds. During the eclipse the direction and velocity of the wind remained constant,

whilst the meteorological observations of Mr. Upton showed a slight rise in barometric pressure, a rise in humidity, and a fall of temperature, the latter reaching even the nightly values, whilst radiation thermometers showed that the heat received by the earth was almost *nil*.

The observations with the photoheliographs which the English observers took out being taken in hand by Lieut. Qualtrough of the American navy.

Perhaps some details as to the work itself may be of interest.

First with regard to the work of Mr. Woods. A red-end collodion plate was washed and placed by him in one of the prismatic camera slides five minutes before totality. Four minutes later he started the clockwork of the integrating spectroscopic slide. Forty seconds before totality exposures were made in the Rowland grating cameras, and at totality the prismatic camera and slit spectroscope were each opened.

In the spectroscopes which were under the care of Mr. Lawrence the exposures commenced ten minutes before totality, his work continuing until ten minutes after totality.

The photoheliographs as we have said were looked after by Lieut. Qualtrough, the plates which he exposed in these instruments being given to Mr. Woods after the eclipse. During the intervals in the exposures of the plates the observers found time to note the corona. In its general character it seems to have much resembled that seen last year in Egypt, but its light was of a more natural tone, the landscape lacking the weird colouring so marked a feature in the Egyptian eclipse

Mr. Lawrence examining the corona with the finder was able to detect much delicate detail, especially in those portions of it near the preceding limb of the moon. He also examined it with a small pocket spectroscope with lens. Taking out the prisms during mid totality he could see the green ring, and very faintly towards the end C and D_3. After totality he still saw the 1474 ring, as well as the red and yellow ones; these latter, however, being as before very faint. Replacing the prisms he could see then only the 1474 line, that examined by Prof. Hastings. The F line, for which he had specially searched, was not seen by him at all. Mr. Lawrence agrees in thinking that the coronal light was of a more natural tint than it was in the eclipse last year. Mr. Dixon of the American party made a careful sketch of the corona, showing five well defined streamers. Soon after totality the photoheliograph clock was stopped, and an endeavour made to obtain the run of the sun's crescent on the two cameras for the purpose of orientation, but, owing to the prevalence of clouds, the attempt was only successful with one, the smaller instrument, with which two exposures were obtained on one plate.

So much for the observations themselves. As to the results we learn that the photographs taken with the small photoheliograph are very good, that which had two minutes exposure showing as much as those which M. Janssen exposed during the whole of totality. The large photoheliograph has not given such good results, all the plates taken showing signs of slight shifts. Still it is believed that, by combining the photographs on each of the nine plates, the whole structure of the corona from the limb to its outmost limits will be obtained.

With the first order grating H and K were obtained as bright lines just before, and immediately after, totality, but with the second order grating no result seems to have been obtained; at least the observers could see nothing when they examined the plate on the island. The photographs taken with the dense prism spectroscope, like those obtained with the first order grating, show bright lines at the commencement and end of totality, particularly at the end, the photograph taken then showing H, K, *h*, *f*, and F very distinctly.

The integrating spectroscope also did useful work. Although no result was obtained during totality with this instrument, the flash of bright lines before and again after totality were successfully photographed by it. The more prominent lines in these photographs are those which belong to hydrogen and the lines H, K, and 1474.

The slit spectroscope was also successful, giving a good photograph from the ultra violet to the green. This spectrum, whilst being in the main a continuous one, is not the same on the two sides of the disk, nor are the lines so numerous as those obtained last year in Egypt. H and K are very strong in the present photograph, but in this respect also the spectrum differs from that obtained in Egypt, these lines then extending across the interval, which is not so in the present photograph. The hydrogen line near G, however, extends over nearly a solar diameter; and *h*, F, 1474, *b*, and other lines have also been obtained.

With regard to the gelatine red-end plates of the prismatic camera, although they gave good photographs, yet the almost entire absence of prominences will diminish their value. In the eclipse of last year, when many prominences were visible, these plates were used with good results. The Rowland grating, too, seems to have given no useful result, but this is probably due, like the small measure of success with the prismatic camera, to the comparative absence of prominences.

In developing the red-end plate immediately after totality Mr. Woods was unfortunate enough, owing to his having to manipulate it almost entirely in the dark, to get it torn, and nothing now remains but the gelatine edging.

The work now being complete, the things began to be repacked for the homeward journey. The *Hartford* returned to Caroline on the 8th, the work of reembarkation commenced, and on the 9th the expedition left.

The observers were almost sorry to leave the island, as their sojourn there had been a most pleasant one. Like most of its kind it is well wooded, the graceful outlines of the cocoanut palms being characteristic features in the pretty scenery which the island affords.

By day the smaller hermit crab swarmed the sandy beach, feeding on what decayed animal matter it could find, whilst at night the large red hermit crabs covered the same beach in their hundreds, they preferring dead vegetable matter. The lagoon too, around which the little islets arrange themselves, was a never-failing source of interest and amusement, and in boating there, and in the deeper water off the reef, or in hunting the shore in search of the brilliant-coloured shells and coral with which the island abounds, the observers found much amusement.

In deep water bivalve shells more than two feet across were observed, whilst the reefs at low water were covered with smaller representatives of the same or a similar species, which threw jets of water into the air. Several octopi were caught by the various members of the expedition, and many beautiful sea-urchins picked up by them in their daily walks. Thus did they spend their spare hours, and it was therefore with some regret that they saw the outlines of the island disappear on their horizon. The *Hartford* was bound for Honolulu in the Sandwich Islands. The voyage was however broken at Hilo, Hawaii, in order that the members of the expedition might visit the celebrated volcano of Kilauea. Honolulu was reached on May 30. Here Messrs. Preston and Brown, who were to continue their pendulum observations remained, the rest of the expedition proceeding in the *Zealandia* for San Francisco. The English observers left at Honolulu copies of the photographs they obtained, to be forwarded to England by the next mail. They left San Francisco on June 15, and may therefore be expected to arrive in England about the end of the present month.

THE ARCHÆOLOGY OF SOUTHERN CALIFORNIA[1]

A VALUABLE contribution to American anthropology has recently appeared, published under the auspices of the U.S. Government, forming the seventh volume of the "Reports of the U.S. Geographical Surveys West of the One Hundredth Meridian." It deals mainly with the remains of the Indians of Southern California, their implements, weapons, vessels, and ornaments.

The observers and collectors were those engaged upon the work of the survey, some of them detailed for work of a different character, but fortunately able to render valuable assistance in explorations for archæological finds.

The letterpress embodies the work of F. W. Putnam, the distinguished curator of the Peabody Museum, whose editorial revision and direction has moulded the whole, that of A. A. Abbott, the veteran explorer of the antiquities of New Jersey, H. C. Yarrow, S. S. Haldeman, A. S. Gatschet, H. W. Henshaw, and Lucien Carr, whose report upon the measurements of the crania from California is most suggestive and important. Besides their own contributions to the principal subject, these gentlemen have freely used the short descriptions of the personal visits of the officers of the army and others to the Pueblo villages of New Mexico and Arizona.

The present inhabitants of Central and Southern California are regarded as a degenerate race deteriorated from an ancestral people of superior parts, and they afford to-day a marked contrast with the more advanced and intelligent races of Northern California. This inferiority has been recognised by all observers, and was comprehended by the Jesuit missionaries, whose unfortunate system, however much its zealous propagation recommended their vigour and sincerity, only helped the natural tendency and hastened the course of a degradation already under way.

As early as 1534 the Spanish explorers invaded this region, and met in many instances a warlike and determined resistance. The priest and missal followed the sword and helmet, and completed the destruction of the people by processes more insidious than those of the warrior, but scarcely less fatal. Missions were established, the natives proselytised, not always by moral suasion, and brought under the control of the missions; they existed in a state of appanage, and became listless and degraded.

The natives of the immediate southern border of California show an improvement over those of Central California, approximating to the superior type in Northern California, a contrast which has so impressed the minds of students as to have started the assumption that the Central Californians belong to a different race, and are to be referred to Malay and Chinese origins. It is however with the description of the implements, utensils, ornaments, &c., of the southern Indians as exhumed from burial mounds, and the story told by such mortuary relics of the habits of their ancestors, that this volume is filled.

Attention had been directed by the Smithsonian Institution to the area upon the coast of California opposite the group of Santa Barbara Islands, and to these islands themselves, as a promising field for archæological search. The indications followed rewarded the Survey with many important objects, enough to permit a conception of the life of their makers.

These latter were in the stone age depending upon stone and bone implements as tools of war, chase, and industry. They seem to have been almost entirely without a knowledge of pottery, but this need may have been scarcely felt from their skill in the manufacture of stone vessels formed from steatite masses, and of all sizes, and adapted to the commonest domestic uses.

This series of objects affords a striking example of their patience and ingenuity. They are described under the designation of "Cooking pots and food vessels." They are in the main oblate spheroidal vessels of soapstone thickened over the base and sides exposed to the heat, and thinning towards the rim of the circular opening upon the top. The smaller specimens are frequently much finished in their smoothness, and vary enough in size and shape to suggest that they were the property of individuals, and prepared and kept for the personal use of their owners. These small vessels often show mending where fractured, a row of holes being perforated upon the two opposite sides of a crack, and the edges drawn together by sinews which are sunk in grooves, over which has been plastered asphaltum. Asphaltum figures in various ways, and was constantly resorted to as a convenient cement; it was employed to fasten their stone-bolts and arrow-heads to their shafts, to attach mouth-pieces to their pipes, the line to their fish-hooks, &c., it formed a surface over their objects upon which ornaments could be imbedded in rude decoration, and figures on their shell beads in spiral lines of black.

Besides the *ollas*, various dish-like utensils are figured with one or more holes for suspension after use, or for removal from the fire, being probably used as baking pans. Stone mortars of basalt and sandstone, small colour mixers, dishes of shell (*Haliotis*), and cups formed of fish vertebræ complete the list of serviceable vessels.

The smoking-pipes, which are carefully studied and described by Dr. Abbott, are long, straight, conical, and sub-cylindrical tubes of steatite, displaying no great variety of form and but inconspicuous attempts at ornamentation. The straight tube corresponding to the bowl of the common pipe is in line with the opening at the insertion of the mouthpiece, and it would seem that tubes of bone or reed inserted for stems must have been curved to permit of their use in any normal position.

The chipped flints are of striking beauty, and will be recognised by all who have examined specimens of ornamental spears and daggers from this region. They are shown of natural size upon two plates of considerable beauty, and vary from 4 inches to 8 or 10 inches in length, lenticular in section, and present ripple-like and corrugated surfaces of very delicate sculpture. The chapters upon perforated stones, miscellaneous objects made of stone, and textile fabrics are especially interesting.

The claim of any great age for these relics seems precluded by their association with glass beads, bronze cups and platters, iron swords, nails, knives, and pistol barrels, all pointing unmistakably to contact with the Spaniards. Yet there can be but little doubt that they perfectly represent the arts of life prevailing among the ancestors of their owners and makers for ages before the appearance of the white man, and that many are themselves heirlooms descended from a great antiquity.

The concluding chapter of Part I. is a suggestive summary of the results of cranial measurements, and the writer, Lucien Carr, indicates the past presence of two races whose intermingling remains are now found upon the Santa Barbara Islands, one—the dolichocephals or long heads—presenting a picture of subjugation and decadence; the other—the brachycephals or short heads—spread over the mainland, occupying the northern islands, and pressing upon the precarious remnant of their predecessors on the southern islands.

Part II. is a diversified compilation of a number of personal narratives of visits to the Pueblo villages, some chapters upon the implements and pottery of their occupants, which seem of a degraded type compared with the productions of their probable ancestors, and a shor

[1] "Report upon the U.S. Geographical Surveys West of the One Hundredth Meridian in charge of First Lieutenant Geo. M. Wheeler." Vol. vii. "Archæology." (Washington, 1879.)

review of cranial measurements. The material seems insufficient and fragmentary, and affords imperfect means for judging in a satisfactory way of the exact status and organisation of these people. A final contribution to the linguistics of the subject, by A. S. Gatschet, closes the volume, with a compendious statement of the relations of the tribes of the western coast with a list of forty vocabularies of western languages.

Finally, this handsome volume, in typography, paper, and illustrations, is of irreproachable beauty, and it treats of a field in archæological study of deep interest and wide import. L. P. GRATACAP

THE SIZE OF ATOMS[1]

II.

IN making brass, if we mix zinc and copper together we find no very manifest signs of chemical affinity at all; there is not a great deal of heat developed: the mixture does not become warm, *it does not explode*. Hence we can infer certainly that contact-electricity action ceases, or does not go on increasing according to the same law, when the metals are subdivided to something like 1/100,000,000 of a centimetre. Now this is an exceedingly important argument. I have more decided data as to the actual magnitude of atoms or molecules to bring before you presently, but I have nothing more decided in *giving for certain a limit to supposable smallness*. We cannot reduce zinc and copper beyond a certain thickness without putting them into a condition in which they lose their properties as wholes, and in which, if put together, we should *not* find the same attraction as we should calculate upon from the thicker plates. I think it is impossible consistently with the knowledge we have of chemical affinities and of the effect of melting zinc and copper together, to admit that a piece of copper or zinc could be divided to a thinness of much less, if at all less, than 1/100,000,000 of a centimetre without separating the atoms or dividing the molecules, or doing away with the composition which constitutes as a whole the solid metal. In short, the structure as it were of bricks, or molecules, or atoms, of which copper and zinc are built up; cannot be much, if at all, less than 1/100,000,000 of a centimetre in diameter, and may be considerably greater.

I will now read you a statement from an article which was published thirteen years ago in NATURE.[2]

"Now let a second plate of zinc be brought by a similar "process to the other side of the plate of copper; a second "plate of copper to the remote side of this second plate of "zinc, and so on till a pile is formed consisting of 50,001 "plates of zinc and 50,000 plates of copper, separated by "100,000 spaces, each plate and each space 1/100,000 of "a centimetre thick. The whole work done by electric "attraction in the formation of this pile is two centimetre-"grammes.

"The whole mass of metal is eight grammes. Hence "the amount of work is a quarter of a centimetre-gramme "per gramme of metal. Now 4030 centimetre-grammes of "work, according to Joule's dynamical equivalent of heat, "is the amount required to warm a gramme of zinc or "copper by one degree Centigrade. Hence the work done "by the electric attraction could warm the substance by "only 1/16,120 of a degree. But now let the thickness of "each piece of metal and of each intervening space be "1/100,000,000 of a centimetre instead of 1/100,000. "The work would be increased a millionfold unless "1/100,000,000 of a centimetre approaches the small-"ness of a molecule. The heat equivalent would therefore "be enough to raise the temperature of the material by "62°. This is barely, if at all, inadmissible, according to "our present knowledge, or, rather, want of knowledge, "regarding the heat of combination of zinc and copper. "But suppose the metal plates and intervening spaces to "be made yet four times thinner, that is to say, the thick-"ness of each to be 1/400,000,000 of a centimetre. The "work and its heat equivalent will be increased sixteen-"fold. It would therefore be 990 times as much as that "required to warm the mass by 1° C., which is very much "more than can possibly be produced by zinc and copper "in entering into molecular combination. Were there in "reality anything like so much heat of combination as this, "a mixture of zinc and copper powders would, if melted in "any one spot, run together, generating more than heat "enough to melt each throughout; just as a large quantity "of gunpowder if ignited in any one spot burns throughout "without fresh application of heat. Hence plates of zinc "and copper of 1/300,000,000 of a centimetre thick, "placed close together alternately, form a near approxima-"tion to a chemical combination, if indeed such thin plates "could be made without splitting atoms."

Similar conclusions result from that curious and most interesting phenomenon, the soap-bubble. Philosophers old and young who occupy themselves with soap-bubbles, have one of the most interesting subjects of physical science to admire. Blow a soap-bubble and look at it, —you may study all your life perhaps and still learn lessons in physical science from it. You will now see on the screen the image of a soap-film in a ring of metal. The light is reflected from the film filling that ring, and focused on the screen. It will show, as you see, colours analogous to those of Newton's rings. As you see the image it is upside down. The liquid streams down (up in the image) and thins away from the highest point of the film. First we see that brilliant green colour. It will become thinner and thinner there, and will pass through beautiful gradations of colour till you see, as now, a deep red, then much lighter, till it becomes a dusky, yellowish white, then green, and blue, and deep violet, and lastly black, but after you see the black spot it very soon bursts. The film itself seems to begin to lose its tension, when it gets considerably less than a quarter of the wave-length of yellow light, which is the thickness for the dusky white, preceding the final black. When you are washing your hands, you may make and deliberately observe a film like this, in a ring formed by the forefingers and thumbs of two hands, and watch the colours. Whenever you begin to see a black spot or several black spots, the film soon after breaks. The film retains its strength until we come to the black spot, where the thickness is clearly much less than 1/60,000 of a centimetre, which is the thickness of the dusky white.

Newton, in the following passage in his "Optics" (pp. 187 and 191 of edition 1721, Second Book, Part I.), tells more of this important phenomenon of the black spot, than is known to many of the best of modern observers.

"Obs. 17.—If a bubble be blown with water, first made "tenacious by dissolving a little soap in it, it is a common "observation that after a while it will appear tinged with a "variety of colours. To defend these bubbles from being "agitated by the external air (whereby their colours are "irregularly moved one among another so that no accurate "observation can be made of them), as soon as I had "blown any of them I covered it with a clear glass, and by "that means its colours emerged in a very regular order, "like so many concentric rings encompassing the top of "the bubble. And as the bubble grew thinner by the con-"tinual subsiding of the water, these rings dilated slowly "and overspread the whole bubble, descending in order to "the bottom of it, where they vanished successively. In "the meanwhile, after all the colours were emerged at the "top, there grew in the centre of the rings a small round "black spot like that in the first observation, which con-"tinually dilated itself, till it became sometimes more than

[1] A lecture delivered by Sir William Thomson at the Royal Institution, on Friday, February 2. Revised by the Author. Continued from p. 205.

[2] See article "On the Size of Atoms," published in NATURE, vol. i. p. 551; printed in Thomson and Tait's "Natural Philosophy," second edition, 1883, vol. i. part 2, Appendix F.

"one-half or three-quarters of an inch in breadth before the "bubble broke. At first I thought there had been no light "reflected from the water in that place, but observing it "more curiously I saw within it several smaller round "spots, which appeared much blacker and darker than the "rest, whereby I knew that there was some reflection at the "other places which were not so dark as those spots. And "by farther trial I found that I could see the images of "some things (as of a candle or the sun) very faintly re-"flected, not only from the great black spot, but also from "the little darker spots which were within it.

"Obs. 18.—If the water was not very tenacious, the "black spots would break forth in the white without any "sensible intervention of the blue. And sometimes they "would break forth within the precedent yellow, or red, "or perhaps within the blue of the second order, before "the intermediate colours had time to display themselves."

Now I have a reason, an irrefragable reason, for saying that the film cannot keep up its tensile strength to 1/100,000,000 of a centimetre, and that is, that the work which would be required to stretch the film a little more than that, would be enough to drive it into vapour.

The theory of capillary attraction shows, that when a bubble—a soap-bubble for instance—is blown larger and larger, work is done by the stretching of a film which resists extension, as if it were an elastic membrane with a constant contractile force. This contractile force is to be reckoned as a certain number of units of force per unit of breadth. Observation of the ascent of water in capillary tubes, shows that the contractile force of a thin film of water, is about sixteen milligrammes weight per millimetre of breadth. Hence the work done in stretching a water film to any degree of thinness, reckoned in millimetre-milligrammes, is equal to sixteen times the number of square millimetres by which the area is augmented, provided the film is not made so thin that there is any sensible diminution of its contractile force. In an article "On the Thermal Effect of Drawing out a Film of Liquid," published in the *Proceedings* of the Royal Society for April, 1858, I have proved from the second law of thermodynamics that about half as much more energy, in the shape of heat, must be given to the film, to prevent it from sinking in temperature while it is being drawn out. Hence the intrinsic energy of a mass of water in the shape of a film kept at constant temperature, increases by twenty-four milligramme-millimetres for every square millimetre added to its area.

Suppose then a film to be given with a thickness of a millimetre, and suppose its area to be augmented ten thousand and one fold: the work done per square millimetre of the original film, that is to say, per milligramme of the mass, would be 240,000 millimetre-milligrammes. The heat equivalent of this is more than half a degree Centigrade (0·57°) of elevation of temperature of the substance. The thickness to which the film is reduced on this supposition, is very approximately 1/10,000 of a millimetre The commonest observation on the soap-bubble, shows that there is no sensible diminution of contractile force, by reduction of the thickness to 1/10,000 of a millimetre; inasmuch as the thickness which gives the first maximum brightness, round the black spot seen where the bubble is thinnest, is only about 1/8,000 of a millimetre.

The very moderate amount of work shown in the preceding estimates, is quite consistent with this deduction. But suppose now the film to be farther stretched, until its thickness is reduced to 1/10,000,000 of a millimetre (1/100,000,000 of a centimetre). The work spent in doing this is two thousand times more than that which we have just calculated. The heat equivalent is 280 times the quantity required to raise the temperature of the liquid by one degree Centigrade. This is far more than we can admit as a possible amount of work done in the extension of a liquid film. It is more than half the amount of work, which if spent on the liquid, would convert it into vapour at ordinary atmospheric pressure. The conclusion is unavoidable, that a water-film falls off greatly in its contractile force, before it is reduced to a thickness of 1/10,000,000 of a millimetre. It is scarcely possible, upon any conceivable molecular theory, that there can be any considerable falling off in the contractile force, as long as there are several molecules in the thickness. It is therefore probable that there are not several molecules in a thickness of 1/10,000,000 of a millimetre of water.

Now when we are considering the subdivision of matter, look at those beautiful colours which you see in this little casket, left, I believe, by Prof. Brand to the Royal Institution. It contains polished steel bars, coloured by having been raised to different degrees of heat, as in the process of annealing hard-tempered steel. These colours, produced by heat on other polished metals besides steel, are due to thin films of transparent oxide, and their tints, as those of the soap-bubble and of the thin space of air in "Newton's rings," depend on the thickness of the film, which, in the case of oxidisable metals, forms by combination with the oxygen of the air, under the influence of heat—a true surface-burning.

You are all familiar with the brilliant and beautifully distributed fringes of heat-colours on polished steel grates and fire-irons, escaping that unhappy rule of domestic æsthetics, which too often keeps those articles glittering and cold and useless, instead of letting them show the exquisite play of warm colouring, naturally and inevitably brought out, when they are used in the work which is their reason for existence. The thickness of the film of oxide which gives the first perceptible colour, a very pale orange or buff tint, due to the enfeeblement or extinction of violet light and enfeeblement of blue, and less enfeeblement of the other colours in order, by interference of the reflections from the two surfaces of the film, is about 1/100,000 of a centimetre, being something less than a quarter wave-length of violet light in the oxide.

The exceedingly searching and detective efficacy of electricity comes to our aid here, and by the force as it were spread through such a film, proves to us the existence of the film when it is considerably thinner than that 1/100,000 of a centimetre, when in fact it is so very thin as to produce absolutely no perceptible effect on the reflected light, that is to say, so thin as to be absolutely invisible. If in the apparatus for measuring contact electricity, of which the drawing is before you (NATURE, vol. xxiii. p. 567), two plates of freshly polished copper be placed in the Volta condenser, a very perfect zero of effect is obtained. If, then, one of the plates be taken out, heated slightly by laying it on a piece of hot iron, and then allowed to cool again and replaced in the Volta condenser, it is found that negative electricity becomes condensed on the surface thus treated, and positive electricity on the bright copper surface facing it, when the two are in metallic connection. If the same process be repeated with somewhat higher temperatures, or somewhat longer times of exposure to it, the electrical difference is augmented. These effects are very sensible before any perceptible tint appears on the copper surface as modified by heat. The effect goes on increasing with higher and higher temperatures of the heating influence, until oxide-tints begin to appear, commencing with buff, and going on through a ruddier colour to a dark-blue slate colour, when no farther heating seems to augment the effect. The greatest contact-electricity effect which I thus obtained between a bright freshly polished copper surface and an opposing face of copper, rendered almost black by oxidation, was such as to require for the neutralising potential in my mode of experimenting[1] about one-half of the potential of a Daniell's cell.

[1] First described in a letter to Joule, published in the *Proceedings* of the Literary and Philosophical Society of Manchester of Jan. 21, 1862, where also I first pointed out the demonstration of a limit to the size of molecules from measurements of contact electricity. The mode of measurement is more fully described in the article of NATURE (vol. xxiii. p. 567), referred to above.

Some not hitherto published experiments with polished silver plates, which I made fifteen years ago, showed me very startlingly, an electric influence from a quite infinitesimal whiff of iodine vapour. The effect on the contact-electricity quality of the surface, seems to go on continuously from the first lodgment, to all other tests quite imperceptible, of a few atoms or molecules of the attacking substance (oxygen, or iodine, or sulphur, or chlorine, for example), and to go on increasing until some such thickness as 1/30,000 or 1/40,000 of a centimetre is reached by the film of oxide or iodide, or whatever it may be that is formed.

The subject is one that deserves much more of careful experimental work and measurement than has hitherto been devoted to it. I allude to it at present to point out to you how it is that by this electric action, we are enabled as it were to sound the depth, of the ocean of molecules attracted to the metallic surface, by the vapour or gas entering into combination with it.

When we come to thicknesses of considerably less than a wave-length, we find solid metals becoming transparent. Through the kindness of Prof. Dewar, I am able to show you some exceedingly thin films, of measured thicknesses of platinum, gold, and silver, placed on glass plates. The platinum is of $1\cdot9 \times 10$ thickness, and is quite opaque;

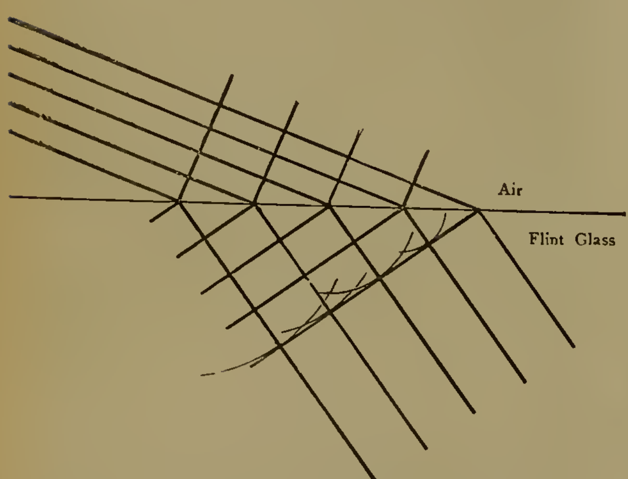

Fig. 3.—Diagram of Huyghen's construction for wave front of refracted light. Drawn for light passing from air to flint glass.

but here is a gold film of about the same thickness, which is transparent to the electric light, as you see, and transmits the beautiful green colour, which you see on the screen. The thickness of this gold (1·9, or nearly 2) is just half the wave-length of violet light in air. This transparent gold, transmitting green light to the screen as you see, at the same time reflects yellow light to the ceiling. Now I will show you the silver. It is thinner, being only $1\cdot5 \times 10^{-5}$ of a centimetre thick, or 3/8 of the air-wave-length of violet light. It is quite opaque to the electric light, so far as our eyes allow us to judge, and reflects all the light up to the ceiling. It is not wonderful that it should be opaque; we might wonder if it were otherwise; but there is an invisible ultra-violet light of a small range of wave-lengths, including a zinc-line of air wave-length $3\cdot4 \times 10^{-5}$, which this silver film transmits. For that particular light the silver film of $1\cdot5 \times 10^{-5}$ thickness is transparent. The image which you now see on the screen, is a magic lantern representation of the self-photographed spectrum, of light that actually came through that silver. You see the zinc-line very clear across it near its middle. Here then we have gold and silver transparent. The silver is opaque for all except that very definite light of wave-lengths from about 3·07 to 3·32.

The different refrangibility of different colours, is a result of observation, of vital importance in the question of the size of atoms. You now see on the screen before you a prismatic spectrum; a well-known phenomenon produced by the differences of the refractions of the different colours, in traversing the prism. The explanation of it in the undulatory theory of light, has taxed the powers of mathematicians to the utmost. Look first, however, to what is easy, and made clear by that diagram (Fig. 3) before you; and you will easily understand that refraction depends on difference of velocity of propagation of light, in the two transparent mediums concerned. The

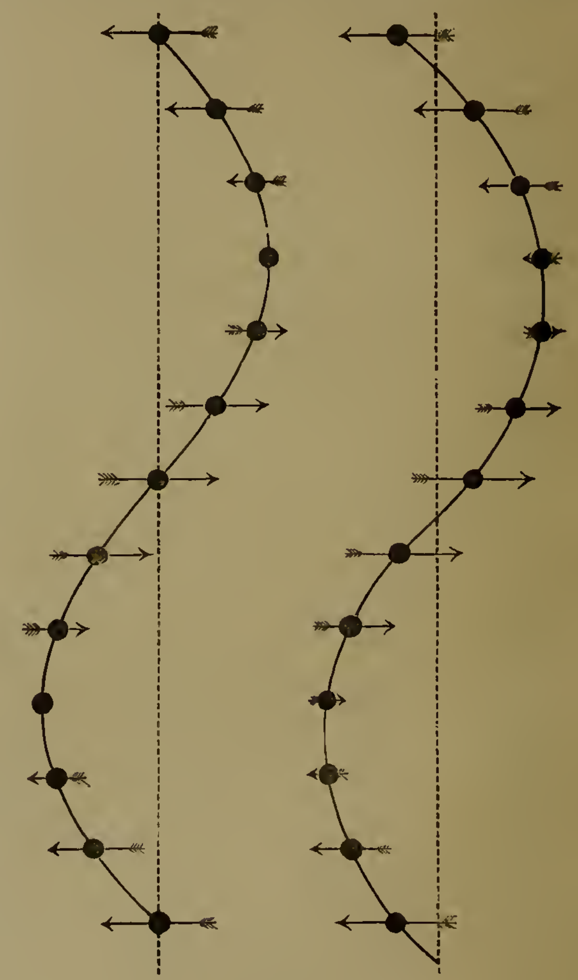

Fig. 4. Fig. 5.
Twelve particles in Wave-Length.

angles in the diagram are approximately correct, for refraction at an interface between air or vacuum and flint glass; and you see that in this case, the velocity of propagation is less in the denser medium. The more refractive medium (not always the denser) of the two, has the less velocity for light transmitted through it. The "refractive index" of any transparent medium, is the ratio of the velocity of propagation in the ether, to the velocity of propagation in the transparent substance.

Now, that the velocity of the propagation of light should be different in different mediums, and should in most cases be smaller in the denser than in the less dense medium, is quite what we should, according to dynamical principles, expect from any conceivable constitution of the

luminiferous ether and of palpable transparent substance. But that the velocity of propagation in any one transparent substance, should be different for light of different colours, that is to say, of different periods of vibration, is not what we should expect; and could not possibly be the fact if the medium is homogeneous, without any limit as to the smallness of the parts of which the qualities are compared. The fact that the velocity of propagation *does* depend on the period, gives what I believe to be irrefragable proof, that the substance of palpable transparent matter, such as water, or glass, or the bisulphuret of carbon of this prism whose spectrum is before you, is not infinitely homogeneous; but that on the contrary, if contiguous portions of any such medium, any medium in fact which can give the prismatic colours, be examined at intervals not incomparably small in comparison with the wave-lengths, utterly heterogeneous quality will be discovered; such heterogeneousness as that which we understand in palpable matter, as the difference between solid and fluid; or between substances differing enormously in density; or such heterogeneousness as differences of velocity and direction of motion, in different positions of a vortex ring in an homogeneous liquid; or such differences of material occupying the space examined, as we find in a great mass of brick building when we pass from brick to brick through mortar (or through *void*, as we too often find in Scotch-built domestic brick chimneys).

Cauchy was I believe the first of mathematicians or naturalists, to allow himself to be driven to the conclusion, that the refractive dispersion of light can only be accounted for, by a finite degree of molecular coarse-grainedness, in the structure of the transparent refracting matter; and as, however we view the question, and however much we may feel compelled to differ, from the details of molecular structure and molecular inter-action assumed by Cauchy, we remain more and more surely fortified in his conclusion, that finite grainedness of transparent palpable matter, is the cause of the difference of the velocity of different colours of light propagated through it, we must regard Cauchy as the discoverer of the dynamical theory of the prismatic colours.

But now we come to the grand difficulty of Cauchy's theory;[1] look at this little table (Table II.), and you will see

TABLE II.—*Velocity* (V) *according to Number* (N) *of Particles in Wave Length*

N	$V\left(=100\,\frac{\sin(\pi/N)}{\pi/N}\right)$
2	63·64
4	90·03
8	97·45
12	98·86
16	99·36
20	99·59
∞	100·00

in the heading, the formula which gives the velocity, in terms of the number of particles to the wave-length, supposing the medium to consist of equal particles arranged in cubic order, and each particle to attract its six nearest neighbours, with a force varying directly as the excess of the distance between them, above a certain constant line (the length of which is to be chosen, according to the degree of compressibility possessed by the elastic solid, which we desire to represent by a crowd of mutually interacting molecules). If you suppose particles of real matter arranged in the cubic order, and six steel wire spiral springs or elastic indiarubber bands, to be hooked on to each particle and stretched between it and its six nearest neighbours, the postulated force may be produced in a model with all needful accuracy; and if we could but successfully wish the theatre of the Royal Institution, conveyed to the centre of the earth, and kept there for five minutes, I should have great pleasure in showing you a model of an elastic solid thus constituted, and showing you waves propagated through it, as are waves of light in the luminiferous ether. Gravity is the inconvenient accident of our actual position, which prevents my showing it to you here just now. But instead, you have these two wave-models (see Fig. 2 above), each of which shows you the displacements and motions of a

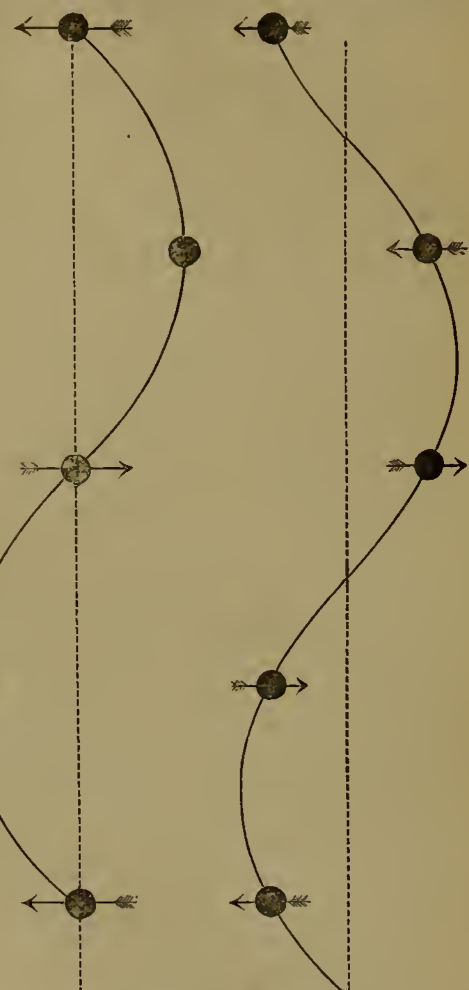

FIG. 6. FIG. 7.
Four particles in Wave-Length.

line of particles, in the propagation of a wave through our imaginary three-dimensional solid; the line of molecules chosen being those which, in equilibrium, are in one direct straight line of the cubic arrangement, and the supposed wave having its wave front perpendicular to this line, and the direction of its vibration, the direction of one of the other two direct lines of the cubic arrangement.

You have also before you this series of diagrams (Figs. 4 to 9) of waves in a molecularly-constituted elastic solid. These two diagrams (Figs. 4 and 5) illustrate a wave in which there are twelve molecules in the wave-length; this one (Fig. 4) showing (by the length and position of the arrows) the magnitude and direction of velocity of each molecule, at the instant when one of the

[1] For an account of the dynamical theory of the "Dispersion of Light," see "View of the Undulatory Theory as Applied to the Dispersion of Light," by the Rev. Baden Powell, M.A., &c. (London: 1841)

molecules is on the crest of the wave, or has reached its maximum displacement; that one (Fig. 5) showing the magnitude and direction of the velocities, after the wave has advanced such a distance, as (in this case equal to one-twenty-fourth of the wave-length) to bring the crest of the wave to midway between two molecules. This pair of diagrams (Figs. 6 and 7) shows the same for waves having four molecules in the wave-length, and this pair (Figs. 8 and 9) for a wave having two molecules in the wave-length.

The more nearly this critical case is approached, that is to say the shorter the wave-length, down to the limit of twice the distance from molecule to molecule, the less becomes the difference between the two configurations of

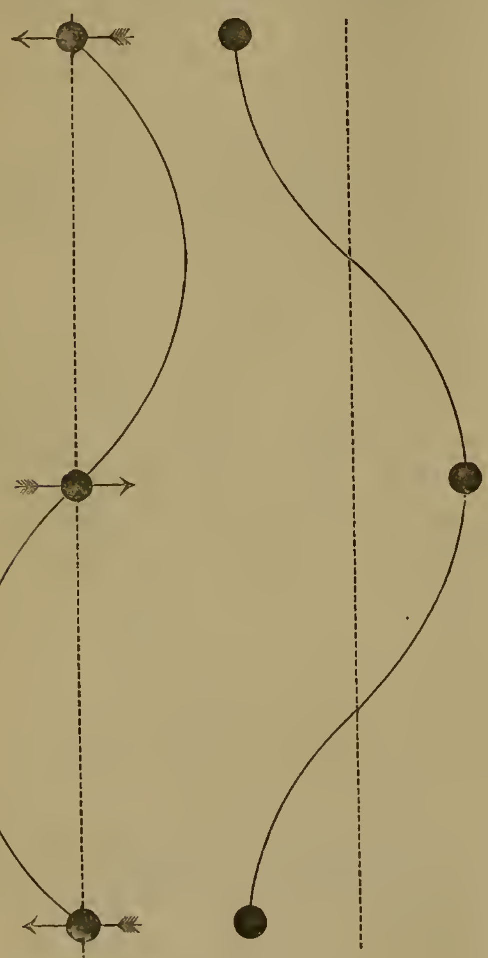

FIG. 8. FIG. 9.
Two particles in Wave-Length.

motion, constituted by waves travelling in opposite directions. In the extreme or critical case, the difference is annulled, and the motion is not a wave-motion, but a case of what is often called "standing vibration." Before I conclude this evening, I hope to explain in detail the kind of motion which we find instead of wave-motion (become mathematically imaginary), when the vibrational period of the exciter is anything less than the critical value; because this case is of extreme importance and interest in physical optics, according to Stokes' hitherto unpublished explanation of phosphorescence.

This supposition of each molecule acting with direct force only on its nearest neighbour, is not exactly the postulate on which Cauchy works. He supposes each molecule to act on all around it, according to some law of rapid decrease as the distance increases; but this must make the influence of coarse-grainedness on the velocity of propagation smaller than it is on the simple assumption, realised in the models and diagrams before you, which therefore represents the extreme limit of the efficacy of Cauchy's unmodified theory to explain dispersion.

Now, by looking at the little table (Table II.) of calculated results, you will see that with as few as 20 molecules in the wave-length, the velocity of propagation is 99½ per cent. of what it would be with an infinite number of molecules; hence the extreme difference of propagational velocity, accountable for by Cauchy's unmodified theory in its idealised extreme of mutual action limited to nearest neighbours, amounts to 1/200. Now look at this table (Table III.) of refractive indices, and you see that the difference of velocity of red light (A), and of violet light (H), amounts in carbon disulphide to 1/17; in dense flint glass to nearly 1/30; in hard crown glass to 1/73; and in water and alcohol to rather more than 1/100. Hence, none of these substances can have so many as 20 molecules in the wave-length, if dispersion is to be accounted for by Cauchy's unmodified theory, and by looking back to the little table of calculated results (Table II.), you will

TABLE III.—*Table of Refractive Indices.*

Line of Spectrum.	Material.				
	Hard Crown Glass.	Extra dense Flint Glass.	Water at 15° C.	Carbon Disulphide at 11° C.	Alcohol at 15° C.
A	1·5118	1·6391	1·3284	1·6142	1·3600
B	1·5136	1·6429	1·3300	1·6207	1·3612
C	1·5146	1·6449	1·3307	1·6240	1·3621
D	1·5171	1·6504	1·3324	1·6333	1·3638
E	1·5203	1·6576	1 3347	1·6465	1·3661
b	1·5210	1·6591	—	—	—
F	1·5231	1·6442	1·3366	1·6584	1·3683
G	1·5283	1·6770	1·3402	1·6836	1·3720
h	1·5310	1·6836	—	—	—
H	1·5328	1·6886	1·3431	1·7090	1·3751

The numbers in the first two columns were determined by Dr. Hopkinson, those in the last three by Messrs. Gladstone and Dale. The index of refraction of air for light near the line E is 1·000294.

see that there could not be more than twelve molecules in the wave-length of violet light in water or alcohol; say ten in hard crown glass; eight in flint glass; and in carbon disulphide actually not more than four molecules in the wave-length, if we are to depend upon Cauchy's unmodified theory for the explanation of dispersion. So large coarse-grainedness of ordinary transparent bodies, solid or fluid, is quite untenable. Before I conclude I intend to show you, from the kinetic theory of gases, a *superior limit* to the size of molecules, according to which, in glass or in water, there is probably something like 600 molecules to the wave-length; and almost certainly *not fewer* than two, or three, or four hundred. But even without any such definite estimate of a superior limit to the size of molecules, there are many reasons against the admission that it is probable or possible. there can be only four, or five, or six to the wave-length. The very drawing by Nobert of 4,000 lines on a breadth of a millimetre, or at the rate of 40,000 to the centimetre, or about two to the ether wave-length of blue (F) light,[1] seems quite to negative the idea of any such possibility, of only five or six molecules to the wave-length, even if we were not to declare against it from theory and observation of the reflection of light from polished surfaces.

STELLAR PHOTOGRAPHY AT HARVARD

AT the meeting of the Astronomical Society which was held on June 8 last, Prof. Pickering of Harvard College Observatory, so well known for his stellar observations, and who is a Foreign Associate of the Society, attended and gave an interesting account of the work which has been done during the past few years at his observatory.

Some few years ago Prof. Pickering took up the work of determining the intensity of the light of the principal stars by eye observation, without taking the question of colour into consideration, work which has been already dwelt upon in this journal. For this purpose he used a photometer, completing his observations, which number some 90,000, about a year ago, and a large part of his results are already in print. The published results of the more important investigators of star magnitudes, from the time of Almagest and Lûfi, have also been reduced. Sir W. Herschel's observations, which appeared almost a century ago in the *Philosophical Transactions*, have likewise been taken in hand at Harvard Observatory and completely discussed. Sir John Herschel's works, the "Uranometria Nova," the "Durchmusterung," as well as many other works in the same field, have also been made use of in preparing the Harvard Catalogue, which therefore shows those cases in which the photometric observations carried out by Prof. Pickering differ from the results obtained by other observers, when their observations are reduced to the same system. These eye observations of stars having been completed, Prof. Pickering, in conjunction with his brother, Mr. W. H. Pickering, has taken up stellar photography from the same point of view. By this means a comparison is obtained between the brightness of the star as seen by the eye, and its brightness as determined by its greater or less action upon the photographic plate; and by a comparison of photographs taken on different nights any variation in brightness may be detected; whilst the exact positions of stars may of course be more accurately and permanently recorded than by eye observations. Mr. A. A. Common recently, by taking photographs of the nebula in Orion on different nights and comparing them, has thus been able to detect a probable variation in one of the stars in the nebula, and in 1858 Professor George P. Bond, by measuring the diameters of stars in photographs was able to determine the relative brightness of the two stars which form the double ζ Ursæ Majoris.

But the work at Harvard University was to do more than this. The stars which Prof. Bond examined were close together. Prof. Pickering wished to compare stars far removed from each other. For this purpose the ordinary method of stellar photography, by which photographs are taken at the foci of large telescopes, would not suffice. These photographs only comprise a small region of but one or two degrees in diameter. A different method was therefore employed in the Harvard observations. A wholly different form to the ordinary equatorial telescope was used. It is not unusual to construct photographic cameras to take pictures of buildings which subtend an angle of 60° or even 90°. But when applied to the stars, however, the images at the edges are very poor, and only very small apertures can be used. It has, however, been found that some of the best lenses for pictures can be obtained covering a circle of 20° diameter without serious distortion, and at the same time large apertures can be used, thus reducing the time of exposure. In order to still further this work, Mr. W. H. Pickering investigated the sensitiveness of various photographic plates, and obtained some so sensitive that stars of the fifth and sixth magnitude have been photographed without using clockwork, they forming dots or making lines, as their images pass across the photographic plate, the length of these lines depending of course upon the time during which the plate is exposed. If the plate be exposed during ten seconds a distinct dot is obtained, whilst an exposure of thirty seconds causes a short line to be formed. The plates used at Harvard Observatory are six by eight inches. They are divided into six equal parts, each part being in turn exposed. By this means six regions of the heavens, each about 15° square, may be photographed on one plate; and by a variation in the dot and line system employed, sometimes taking the dot and sometimes the line first, three pictures may be taken on a single division of one of the plates without giving rise to any confusion. Instead of simply six, therefore, eighteen photographs are taken on one of these plates, so that on a single plate a portion of the heavens of more than three hours' right ascension, and extending from 30° S. to 60° N., may be included. Since each portion of the plate covers a region of about 15°, the camera mounting has a series of notches or stops, by which it may be instantly moved through that amount either of right ascension or declination.

When photographing the following is the exact method employed. The first exposure takes the region between 30° and 15° south declination, and between one hour and a half and half an hour west of the meridian. First the plate is exposed for ten seconds, and each star records itself by a dot. The plate is then covered for ten seconds; next it is exposed for a period of thirty seconds, and each star makes a line on the plate. By means of the clamping arrangement to which we have referred the plate is then moved through one hour in right ascension. This takes up the remaining few seconds of the minute, so that the taking of the next photograph begins with the first second of another minute. The camera is then on the meridian. The same part of the plate is again exposed, and in order to distinguish this series of stars from those first photographed, this time the plate is exposed first during thirty seconds, and then during ten, so that the result is a line followed by a dot. This gives the second series. But the same portion of the plate may be again used. The remaining ten seconds of the second minute, like those of the first, are spent in moving the camera through another hour of right ascension. Then a fresh exposure is made for thirty seconds, a line simply being obtained without a dot, and this completes the series. The first class of images is in dots and lines, the second in lines and dots, the third is recognised by the presence of lines alone. The thirty seconds which remain of the third minute are employed in exposing a second portion of the plate, and changing the position of the camera, which now takes in the region from 15° S. to the equator. The same process is then gone through again, three exposures as before being made in three different positions of right ascension. By continuing this process, taking three photographs on each of the six portions into which the plate is divided, the whole region included between the declinations of $-30°$ and $+60°$, and between three hours of right ascension, $1\frac{1}{2}$ hours on each side of the meridian, being one eighth of the whole heavens, excluding the circumpolar stars, will be photographed on one plate, the whole operation occupying but eighteen minutes. With regard to those stars in the vicinity of the Pole, some other method will have to be adopted. Thus much for one branch of the work—and an important branch—carried on at Harvard Observatory.

Another portion of their work consists in the preparation of a photographic map of the entire heavens. The method just described, in which clockwork is dispensed with, only enables those stars whose magnitude is not less than five or six to be photographed, and stars of a less magnitude than this must of course be included in a map of the heavens. The camera in this work, therefore, is driven by clockwork. By this means stars of the eighth magnitude record their images on the photographic plate, and as many as 200 are visible in the paper print within a

circle of 5° in diameter. A photograph taken in this way of a portion of the constellation of Orion, besides showing the three stars of the Belt and the Sword-Handle, gives an interesting picture of the nebula.

With reference to the question of the colours of stars it is interesting to note the faintness of α Orionis in the photographs. To the eye its brilliancy is almost as great as that of β, whilst in the photograph it is not more prominent than λ. The reason is to be found in the colour of α. It is a red star, and consequently makes but little impression on the photographic plate.

Again, in the constellation Cetus the three stars which are brightest to the eye are α, γ, and δ. A, which is the brightest of the three, has close to it a very faint companion, scarcely visible to the naked eye, its magnitude being given as 6·3, whilst that of α is 2·7. This is the appearance of this part of that constellation as seen by the eye. A photograph of this region was taken at Harvard with the result that the small star is seen in the photograph nearly as bright as α, it being only three-tenths of a magnitude less. The colour of these stars again explains this, α being of a reddish tint, whilst the small star is of a deep blue colour, and being so the rays which flow from it have a greater influence on the photographic plate. A comparison of the number of stars seen in the photograph of Orion with the number in the photometric catalogue, further illustrates this effect of colour. In that part of this constellation included between 5° north and 5° south declination, and 75° to 90° of right ascension, sixteen stars were common to photograph and catalogue; a like number, being either too small in magnitude or too red in colour, although catalogued, remain unrecorded on the photographic plate; whilst five others seen in the photograph are not given in the catalogue. A reduction has been made of the results given by the plates of different makers, with the view of ascertaining the value of the deviation. In two of such plates the average deviation was 0·21 of a magnitude, and in two measurements of the same plate it was found to be 0·07 of a magnitude.

It is obvious from this account of the work at Harvard that star photography is entering into a new phase, and one which will entirely replace the present system of eye observations, for the reason that, whilst the eye is so variable, photographic plates may now be obtained, doing their work with almost definite wave-lengths of light. The constant record of the plate, must in time therefore be preferred to observation by the variable eye. At the same time as photography advances, if it be considered necessary to obtain photographic star maps to record the observations of the average eye, there will be no difficulty in this being done.

NOTES

IN accordance with the provisions of the Statutes, the Council of the Royal Society met last Thursday to elect one from among themselves to fill the office of president until the annual election on November 30. The choice, as had been anticipated, fell upon Prof. Huxley. We believe that this *ad interim* election has given the greatest satisfaction to all the Fellows of the Society.
